Twin studies to determine the genetic component of the threshold character are based on comparing *concordance rates* of MZ and DZ twins. If both members of a twin pair have the same status of a dichotomous trait (i.e. either both have the disease or both do not have the disease), they are *concordant*. If they do not share the trait status, they are *discordant*. The concordance rate is the proportion of concordant twin pairs among all those with the trait. Significantly higher concordance rates in MZ twins compared with DZ twins is considered an evidence for a significant genetic component of the disease. The significance of the difference can be easily tested by a  $2 \times 2$  contingency table using a chi-square test (see Table 12-3).

However, concordance rates are not appropriate for continuous traits, so correlation coefficients can be used instead of concordance rates (12).

The method to determine the degree of genetic component of a continuous trait is based on a comparison of the variance of the differences between MZ twins and differences between DZ twins. As MZ twins share all their genes, the variance of the trait between MZ twins ( $V_{MZ}$ ) must be due to environmental variance ( $V_E$ ), so in this case, we have  $V_{MZ} = V_E$ . However, the variance of the trait between the DZ twins ( $V_{DZ}$ ) could be due to both environment ( $V_E$ ) and shared genes ( $V_G$ ). So, genetic variance is  $V_G = V_{DZ} - V_{MZ}$ , and therefore, the *heritability*,  $h^2$ , is defined as

$$h^2 = \frac{V_{DZ} - V_{MZ}}{V_{DZ}}$$

Heritability ranges between 0 and 1, with 0 meaning a solely environmentally determined trait and 1 meaning a completely genetically determined trait.

Adoption studies provide a second familial aggregation strategy for estimating the influence of genes on

multifactorial traits. The strategy consists of comparing disease rates among the adopted offspring of affected parents with the rates among adopted offspring of unaffected parents. Certain biases can influence these studies, namely, (1) parental environment could have long-lasting effects on an adopted child; (2) adoption agencies attempt to match the adoptive parents with natural parents in terms of socioeconomic status; (3) children might be several years old when adopted, introducing the potential for many environmental confounds. Moreover, these studies are reasonably good at estimating additive genetic effects that are not age specific, but poor at estimating nonadditive genetic effects or genetic effects that are expressed differently across the age span.

For continuous traits, the familial aggregation is usually measured by heritability, which is the proportion of variability of the trait explained by genetic variation. Heritability can be defined as either using total genetic effects (sum of additive, dominant, and epistatic effects) or using only additive effects. The former quantity is called *heritability in the broad sense* and is given by

$$h^2 = \frac{\text{Var}(G)}{\text{Var}(T)},$$

where  $\text{Var}(G)$  and  $\text{Var}(T)$  are genetic and total variance, respectively. The latter quantity is called *heritability in the narrow sense* and is given by

$$h^2 = \frac{\text{Var}(A)}{\text{Var}(T)},$$

where  $\text{Var}(A)$  is the additive genetic variance.

One cannot conclude the number of genes or which genes are involved in the etiology of the trait from a heritability estimate. Although the absence of familial aggregation is generally thought to rule out a genetic contribution the trait, there are some unlikely yet plausible scenarios where this is not so, including but not limited to phenotypic competition within families (13) that counters genetic effects, and an extreme form of epistasis referred to by some as *emergence* (14). It is also important to emphasize that heritability is a population-specific estimate, and thus can vary from population to population.

There are many other methods to detect and estimate familial aggregation using family data. For example, the recurrence risk is often used to determine the strength of familial aggregation for a discrete trait. The recurrence risk is the probability that a relative of an affected individual is also affected. The most commonly used measure is the sibling recurrence risk, i.e. the probability that a sibling of an affected individual is also affected. The ratio of the sibling recurrence risk and the overall disease prevalence is called a *sibling relative risk*. It is one of the measures of the magnitude of the genetic contribution to susceptibility for a dichotomous trait (affected versus unaffected). Examination of relative recurrence risk values for various classes of relatives could suggest that

the trait is influenced by multiple loci (15). For a single ascertainment scheme, the sibling recurrence risk can be calculated from sibling data as follows (16):

$$K_s = \frac{\sum_{s=1} \sum_{a=1} (a-1)n_{s(a)}}{\sum_{s=1} \sum_{a=1} (s-1)n_{s(a)}}$$

where  $a$  = number of affected sibs in a sibship,  $s$  = number of siblings in the sibship, and  $n_{s(a)}$  = number of sibships of size  $s$  with  $a$  affected sibs.

Note that the familial aggregation methods given above use only trait information from the sample. Owing to the availability of genome-wide single nucleotide polymorphism (SNP) data, it is now feasible to calculate the heritability using genome-wide SNP markers. One such method was proposed by Visscher et al. (17), who used genome-wide identity-by-descent (IBD) sharing probability between full sibs using genome-wide SNPs data.

### 12.3.2 Segregation Analysis

Once a genetic basis of the trait has been established, traditionally, the next step has been to determine the genetic models that explain the segregation of a phenotype (continuous, dichotomous, or ordinal) in a given familial data set via segregation analysis. Segregation analysis requires phenotypic data on related individuals and does not require any molecular data. Segregation analysis is the statistical methodology to determine whether a model with one or more major genes and/or polygenes (i.e. a set of genes each with small quantitative effect that together produce a phenotype) is consistent with the observed pattern of phenotypic inheritance, and to estimate the parameters of the best-fitting genetic model. It entails determining the mode of inheritance (additive, recessive, or dominant), estimating “disease” allele frequency, and estimating penetrances (probability of being affected given genotype). At one time, segregation analysis was one of the most important tools for genetic analysis of familial data. In the late 1980s, large numbers of DNA markers became available, which rendered segregation analysis less popular.

If the trait is monogenic and thus owing to single major gene effect, segregation analysis has proven to be a very effective tool in determining the parameters for mode of inheritance. Subsequently, these parameters have been used in model-based linkage analysis (see below for more detail) to find the location of putative disease-causing genes. This paradigm has been used successfully for the simple Mendelian traits, in which only one gene is segregating. For multifactorial traits, which may be due to the effects of many genes and environmental effects, estimation of the genetic model may be virtually impossible using segregation analysis.

In order to determine the parameters of the genetic model using segregation analysis, the likelihood of a particular mode of inheritance can be formulated using three types of probability functions. First, there is a

probability distribution for segregation of genotypes among the founders (individuals whose parents are not included in the observed pedigree data), where genotypes of the founders are independently drawn from the population based on the prevalence of the disease and mode of inheritance. Second, there is a probability distribution of the segregating genotypes of the non-founders (individuals with both parents in the pedigree) conditional on their parental genotypes. Third, there are penetrance functions (probability of being affected given a particular genotype). To test whether there is a segregation of a single gene, the likelihood under the assumed genetic model is compared with the likelihood under the null model of segregation with no genetic effect. The more complicated or general model could be included for testing a particular mode of inheritance including polygenic or multifactorial components in modeling the disease. However, the number of possible genetic models with a given mode of inheritance may be too large to make any meaningful inference about the disease model.

### 12.3.3 Linkage Analysis

Genetic linkage analysis is based on the observation that any two loci, which are in close proximity to each other on the same chromosome, will tend to cosegregate among related individuals more often than two random loci in the genome. Thus, the affected individuals sharing a genotype at a putative disease locus would be more likely to share a genotype at linked marker loci. In the absence of linkage, the recombination fraction (i.e.  $\theta$  = the proportion of gametes in which two genes on the same parental chromosome are separated; for more details, see [http://en.wikipedia.org/wiki/Genetic\\_linkage](http://en.wikipedia.org/wiki/Genetic_linkage)) is  $\frac{1}{2}$ ; however, if there is a linkage, the recombination fraction is  $< \frac{1}{2}$ . If we cover the entire human genome using evenly spaced markers across the chromosomes, it will be possible to find marker loci associated with a given trait of interest.

The methods of linkage analysis can be divided into two broad classes: *model-based* (parametric) and *model-free* (sometimes referred to as *nonparametric*) linkage analysis.

**12.3.3.1 Model-Based Analysis.** Model-based methods assume a specific genetic model underlying the trait, and the statistical evidence in favor of linkage with a marker locus is summarized by the maximum value of the *lod score* (18). The lod score is the logarithm of the likelihood ratio of observing a particular set of family data under a specific alternative hypothesis of linkage relative to the null hypothesis of no linkage between disease and marker loci ( $H_0: \theta = \frac{1}{2}$ ). For details of how the likelihood is formulated, see Elston and Stewart (19), Elston and Rao (20), and Lander and Green (21).

This approach has been remarkably successful in identifying genes responsible for Mendelian disorders. In order to calculate such likelihood for families, we must specify a probability model. Several assumptions

are usually made in calculating lod scores: the mode of inheritance underlying the marker and the trait is known, the parameters such as penetrances and allele frequencies at both marker and trait loci are known without error, and all founders are unrelated to each other. Misspecification of any of these assumptions can affect the validity or power of the analysis and can result in an inconsistent estimate of the recombination fraction. Thus, the models used in model-based analysis must approximate the complexity of the disease being investigated. It is noteworthy that incorrect specification of a legitimate model-based linkage test may reduce power but generally does not lead to an inflated Type I error rate (false-positive rate).

**12.3.3.2 Model-Free Linkage Analysis.** The genetic mechanism underlying a complex disease is often unknown, and it is impossible to specify the correct genetic parameters such as mode of inheritance, disease allele frequency, and penetrance in complex diseases. Under these circumstances, model-free linkage analysis, which makes no assumption about the mode of inheritance of the trait, is usually preferred. If a disease susceptibility locus and a marker locus are linked, and, by definition, cosegregating in a family, pairs of relatives who are concordant for the disease (i.e. both affected or neither affected) should share more alleles identical-by-descent (IBD<sup>5</sup>) than will an average pair of relatives with the same degree of kinship. Similarly, discordant (affected–unaffected) relative pairs should share fewer alleles IBD than will an average pair of relatives with the same degree of kinship at the disease locus or marker linked to the disease locus. Model-free methods were first derived for sib pairs (22,23), but were extended to other relative pairs (24,25). The Haseman–Elston method consists of regressing the squared phenotypic difference among siblings within sib pairs on the estimated proportion of alleles the sibs share IBD at a marker locus. A negative slope suggests linkage because it indicates that greater similarity at a trait locus tends to occur with greater similarity at a marker locus. There have been a number of extensions to the Haseman–Elston method to increase its power (26–35). In 2003, *Human Heredity* published special topic issue titled *Recent Advances in the Analysis of Genetic Traits* celebrating the thirtieth anniversary of the seminal paper by Haseman and Elston for quantitative trait linkage analysis (*Human Heredity* 2003, Vol. 55, No. 2–3). Several software programs are available to perform linkage analyses, including S.A.G.E. (36), GENEHUNTER (37), LINKAGE (38–40), Mx (<http://www.vcu.edu/mx/>) and MERLIN (41).

The model-free methods described above mostly utilize relative pairs such as sib pairs. However, large extended families could provide more linkage information than

these relative pairs. Methods based on the variance components framework have become a popular choice for linkage analysis because of ease of modeling covariates and gene–gene or gene–environment interactions, and can utilize large extended families in the model-free environment (42–46). There are several programs available to perform linkage analyses based on variance components methodology such as ACT (43), SOLAR (42), and Mx (<http://www.vcu.edu/mx/>). Mx uses a structural equation modeling approach, which is equivalent to the other types of variance components approaches under most circumstances. There are many more statistical genetics packages freely available for public use, and a complete list along with download information for each package can be found at <http://linkage.rockefeller.edu/soft/> and <http://www.soph.uab.edu/ssg/linkage/lddac>.

### 12.3.4 Transmission Disequilibrium Test and Association Analysis Using Familial Data

In classical genetic studies, the identification of a chromosomal region with linkage analysis is the first step in the gene mapping process. As linkage analysis provides information of a genomic region, a typical quantitative trait locus (QTL) may cover several millions of base pairs and may contain hundreds of genes. The initial detection of the QTL is followed by addition of more markers within the QTL to narrow down the region as much as possible. Once the resolution limit of the linkage approach is reached, the most commonly employed follow-up is to fine map using association analyses with SNPs.

The rationale for association analyses is to confirm the involvement of a putative allele involved in a trait of interest. The rationale of fine mapping is that the greater number of SNPs and the greater sensitivity of the association tests provide more detailed information of the target region. The SNPs located close to a disease locus may cosegregate because of linkage disequilibrium, i.e. allelic association due to linkage. The allelic association forms the theoretical basis for association mapping. Allelic association that is not due to linkage disequilibrium is of no interest in mapping disease genes. The simplest way to test for association is to perform a case–control study, where the cases are the individuals with the disease and the controls are without the disease. Association is then tested by ascertaining whether a particular marker allele is more frequent among the cases than the controls. A significant result will be observed if the marker is in linkage disequilibrium with the disease locus, or from a variety of confounding reasons such as population stratification. Therefore, case–control association studies without controlling for stratification are prone to false-positive results with no biological significance, and for this reason, association studies were not popular until the mid-1990s when methods to account for this stratification were established using familial data (47).

<sup>5</sup>“IBD alleles in an individual or in two people are defined as alleles that are identical because they have both been inherited from the same common ancestor, as opposed to identity-by-state.”—from <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hmg>.

To control for population stratification, Spielman et al. (47) proposed the transmission disequilibrium test (TDT), which is a family-based association test (FBAT) in the presence of linkage that controls for population stratification by comparing the allele frequencies among alleles transmitted to an affected offspring to those that are not transmitted to an affected offspring from informative parental matings (i.e. matings with at least one heterozygous parent). This study design requires the collection of family trios that include two parents and an affected offspring. More than 225 extensions and variations of the original TDT have been proposed (see the exhaustive review of TDT procedures in Tiwari et al. (48)). There are a number of software programs available for TDT and/or association analyses using family data such as FBAT (<http://www.biostat.harvard.edu/~fbat/fbat.htm>), ASSOC (<http://darwin.cwru.edu/sage/>), and GASSOC ([http://mayoresearch.mayo.edu/schaid\\_lab/software.cfm](http://mayoresearch.mayo.edu/schaid_lab/software.cfm)). A complete list of association programs can be found at <http://linkage.rockefeller.edu/> and <http://www.soph.uab.edu/ssg.asp?id=1087>.

Once the results from the association analyses are deemed adequate, the next step is to screen the candidate genes for DNA sequence variation by direct sequencing. The relevance of the detected mutations is confirmed with additional association studies in the original and other populations, as well as functional assays in vitro (expression studies in different cell lines) and in vivo (transgenic and knock-out animal models) (49).

## 12.4 THE INTERNATIONAL HapMap PROJECT

In the context presented above, studies progress from estimates of heritability to segregation analysis to linkage and then finally familial association analysis to determine candidate genes for a trait of interest. However, this paradigm has changed recently. With the advent of high-dimensional genotyping technologies using microarrays, the approach for discovering new genetic variants for a disease or trait have changed drastically. In 1996, Lander proposed the common-disease common-variant (CDCV) hypothesis (50). The HapMap project was initiated to create dense set of genetic markers to test the CDCV hypothesis. The CDCV is based on the idea that the genetic component of common diseases is attributable in part to common allelic variants (i.e. alleles with frequency at least 5%). The draft of the complete human genome sequence was completed in 2001 and had strong effect in advances in the genome sequencing technology (51). The International HapMap Project ([www.hapmap.org](http://www.hapmap.org)) was an international partnership that was formed in 2002 to help researchers find genes associated with human disease by providing a public database of common genome-wide human variation across populations (52–54). The first stage of the HapMap project focused on four diverse populations: 30 trios (two parents and adult child) from Yoruba in Ibadan

(90 individuals), Nigeria, 30 trios from the Centre d'Etude du Polymorphisme Humain (CEPH) collection of Utah residents of Northern and Western European ancestry, 45 unrelated individuals from the Han Chinese in Beijing, and 45 unrelated individuals from Japanese in Tokyo. This project genotyped over 1 million SNPs in Phase I and additional 2.1 million in Phase II in the HapMap samples (53,54). It helped initiate advances in SNP array technologies to make genome-wide association studies (GWAS) feasible and affordable. Affymetrix and Illumina SNP arrays became available to researchers, which initially surveyed approximately 100,000 SNPs, and which now survey 2.5 million SNPs. During the most recent phase, HapMap 3, 1184 individuals representing 11 global populations were genotyped for approximately 1.6 million common SNPs (55; <http://www.sanger.ac.uk/resources/downloads/human/hapmap3.html>; <http://www.broadinstitute.org/~debakker/p3.html>; <http://hapmap.ncbi.nlm.nih.gov/>).

As a complement, the 1000 Genomes Project, which began in 2008, was initiated to provide a catalog of low-frequency SNPs and structural and sequence variants in the human genome (56; <http://www.1000genomes.org/>).

## 12.5 GENOME-WIDE ASSOCIATION STUDIES

GWAS is an approach that involves scanning thousands to a few million SNPs across the whole genome on many individuals to find association with a disease or trait. As mentioned earlier, GWAS became a popular choice of genetic studies to detect putative loci associated with a disease or trait because of availability of high-throughput SNP arrays, decreased cost of genotyping, and methods to correct for population stratification (i.e. systematic differences in allele frequencies between subpopulations in a given population possibly because of different ancestry). Before the HapMap era, investigators were reluctant to conduct association studies using population data because of concerns about population stratification. For example, in case-control studies, we usually test association of a particular SNP by comparing allele frequency between cases and controls. Allele frequencies are known to vary within and between populations depending on genetic ancestry (53,57). Genetic ancestry becomes a confounding variable leading to spurious associations if allele frequencies are different within or between race/ethnic groups. Methods for correcting population substructure are described later.

### 12.5.1 Study Designs

Any type of data set such as pedigree data, case-control data, or population data are all appropriate choices for GWAS, but one has to adjust for familial correlations in pedigree data and population stratification in population or case-control data sets to control for the confounding

due to relatedness or population substructure. Case-control and population data have been commonly used for GWAS because of availability and convenience of ascertainment. There are some issues associated with the case-control design. If the disease is heterogenous, extra attention should be paid to minimize heterogeneity in case selection, e.g. selecting the most extreme cases or selecting individuals from a familial disease cohort. There has been a controversy in how to select optimal controls. Usually, controls from the same population and residing in same geographic area are preferred, but these can be difficult to ascertain. The Wellcome Trust Case Control Consortium used 3000 UK controls and 2000 cases from each of seven different diseases and showed that using common controls was effective, had minimal impact on genotypic distributions, and did not lead to excess false positives (58,59). Misclassification error in control selection could affect the power of the association analysis. Specifically, this is true for late-onset diseases because controls have not yet reached the age to develop the disease; this issue can be resolved by increasing the sample size (58). Population stratification and cryptic relatedness (i.e. relatedness among the individuals in the study that is not known to the investigator) can also increase the false-positive findings as previously discussed. The family-based association studies are robust to population stratification, but it is difficult to ascertain all pedigree members, which leads to missing data within families and loss of power compared to case-control designs (60). There are other issues with study design selection; an excellent review is provided by McCarthy et al. (58).

### 12.5.2 Quality Control

The first step of GWAS analysis is the QC of the genotypic and phenotypic data. There are a number of procedures needed to ensure the quality of genotype data both at the genotyping laboratory and after calling genotypes using statistical approaches. Here, we assume that the genotyping laboratory has used best practices to remove technical variation, and we present only the statistical methods that are used after completion of the genotyping. The QC and association analysis of GWAS data can be performed using the robust, freely available, and open source software PLINK developed by Purcell et al. (61). Two recent publications provide excellent reviews of the QC protocol for GWAS data (62,63). Here, we provide few important steps of the QC in GWAS in similar guidelines as in Laurie et al. (62) and Turner et al. (63). Note that the current genotyping technology is very reliable, but there are still some possibilities of errors when genotyping large number of SNPs.

### 12.5.3 Sex Inconsistency

It is possible that self-reported sex of the individual is incorrect. Sex inconsistency can be checked by comparing

the reported sex of each individual with predicted sex by using X-chromosome markers' heterozygosity to determine the sex of the individual empirically.

### 12.5.4 Relatedness and Mendelian Errors

Another kind of error that can occur in genotyping is due to sample mix-up, cryptic relatedness, duplications, and pedigree errors such as self-reported relationships that are not accurate. To detect sample relatedness, one can calculate three IBD probabilities of sharing 0, 1, and 2 alleles that are identical-by-descent for each pair of individuals using software such as PLINK and a kinship coefficient matrix. Individuals sharing zero alleles at every locus are unrelated, individuals sharing one allele IBD at every locus are parent-offspring pairs, individuals sharing two alleles IBD at every locus are MZ twins or a duplicated sample, and on average, sib pairs share 0, 1, and 2 alleles IBD with sharing probabilities 0.25, 0.5, and 0.25, respectively. The relationship errors can be corrected by consulting with the self-reported relationships and/or using inferred genetic relationships. Cryptic relatedness can inflate the variance of the test statistic (e.g. if the test statistic is the difference in the overall allele counts between case and control samples in a trend test (64)). The presence of cryptic relatedness in case-control studies increases the false positives in association analysis. Devlin and Roeder provided a method to correct for the variance inflation (see References (64) and (65) for details).

### 12.5.5 Batch Effects

For GWAS, samples are processed together for genotyping in a batch. The size and composition of the sample batch depends on the type of the commercial array; for example, an affymetrix array can genotype up to 96 samples, and an Illumina array can genotype up to 24 samples. To minimize batch effects, samples should be randomly assigned to plates with different phenotypes, sex, race, and ethnicity. The downstream association study can be confounded by the batch effects. There are several methods available to detect any batch effects. The most commonly used method is to compare the average minor allele frequencies (MAFs) and average genotyping call rates across all SNPs for each plate. Most genotyping laboratories perform batch effect detection and usually re genotype the data if there is a batch effect or a plate is discarded when there is a large amount of missing data.

### 12.5.6 Marker and Sample Genotyping Efficiency or Call Rate

*Marker genotyping efficiency* is defined as the proportion of samples with a genotype call for each marker. If large numbers of samples is not called for a particular marker, that is, an indication of a poor assay and the marker

should be removed from further analysis. A threshold for removing markers varies from study to study depending on the sample size of the study. Usually recommended call rates are 98–99%. If the quality of the DNA sample is poor, it leads to low call rate of genotypes for the individual, i.e. the number of missing genotypes will be large and the sample should be excluded from further analysis. Before performing the association analysis, one should filter out the samples and markers using some threshold for marker and sample call rates.

### 12.5.7 Population Stratification

There are a number of methods proposed to correct for population substructure. Three commonly used methods to correct for the underlying variation in allele frequencies that leads to confounding due to population stratification are genomic control (4,64–71), structured association testing (72–74), and principal components (PCs) (75,76). The genomic control method controls for confounding due to substructure by estimating an inflation factor (ratio of the variance of the test statistic to the variance under the null hypothesis), then adjusting the test statistics for all markers in GWAS downward by the inflation factor. Usually, the inflation factor is calculated using a few hundred loci. Structure association testing (72,77) (1) estimates ancestry proportions of each individual from the founding population using markers with different allele frequencies in the founder population; and (2) uses these proportions to cluster individuals to create homogenous groups with similar ancestry profile for the association analysis. Principal components analysis (PCA) uses thousands of markers to detect population stratification and PCs then can be used to correct for stratification by modeling PCs as covariates in the model (75,76). PCs can be calculated using a program Eigenstrat (75,76). There are two issues with using PCA: (1) how many SNPs to use, and (2) how many PCs should be included as covariates in the association analysis.

### 12.5.8 Marker Allele Frequency and Hardy–Weinberg Equilibrium Filter

The Hardy–Weinberg equilibrium (HWE) test compares the observed genotypic proportion at the marker versus the expected proportion. Deviation from HWE at a marker locus can be due to population stratification, inbreeding, selection, nonrandom mating, genotyping error, actual association to the disease or trait under study, or a deletion or duplication polymorphism. However, HWE is typically used to detect genotyping errors. SNPs that do not meet HWE at a certain threshold of significance are usually excluded from further association analysis. It is also important to discard SNPs based on MAF. Most GWAS studies are powered to detect a disease association with common SNPs ( $MAF \geq 0.05$ ).

The rare SNPs may lead to spurious results because of the small number of homozygotes for the minor allele, genotyping errors, or population stratification.

## 12.6 ASSOCIATION METHODS/ STATISTICAL ANALYSIS

### 12.6.1 Discovery Phase of the GWAS

Discovery phase consists of scanning the genome with at least 1000 cases and 1000 controls with an appropriate statistical test. The choice of the statistical test for association depends on the study design and the phenotype under consideration. In the case-control design, the goal is to compare the allele or genotypic frequencies between cases (affected) and controls (normal). This can be tested with Pearson's chi-square test, Fisher's exact test, or the Cochran–Armitage test. Pearson's chi-square tests the null hypothesis of no association between rows and columns of the  $2 \times 3$  contingency table consisting of the counts of the three genotypes among cases and controls (78). Fisher's exact test is similar to the Pearson's test, but the deviation from the null hypothesis is calculated exactly from all possible permutations of the data, and thus, does not assume the asymptotic property as Pearson's test (79). The Cochran–Armitage test for trend is a test of proportions of cases versus controls (80–82) and assumes an additive mode of inheritance that is a linear trend. There is a loss of power if the trend is not linear. Freidlin et al. (83) recommended using a maximum of the test statistics obtained from additive, dominant, or recessive effects models. Note that in the above statistical procedures, one cannot model covariates such as sex, age, race, age of onset, PCs (PCs from admixture), and so on. To accommodate any relevant covariates in the analysis, one can use logistic regression. Logistic regression is more flexible in that it can model covariates, multiple SNPs as main effects, SNP by SNP interactions, SNP by environment interactions, and so on. If the phenotype is continuous, analysis of variance and general linear model approaches can be employed. One can also use a linear regression framework if extremes of the distribution are used to define case and control status. Huang and Lin have given an efficient association method using extreme phenotypes (84). The analysis of familial data requires correcting for the dependency of observations. The notable methods include linear mixed model (85–87), FBAT (see review by Laird and Lange (88)), or ASSOC (a module of S.A.G.E. software suite (36)). After scanning 1–2 million SNPs (i.e. 1–2 million statistical tests) to determine significant associations, appropriate multiple testing correction is required to control for false positives and also in choosing SNPs for follow-up studies. The guideline for significant association for GWAS is generally a  $p$  value of  $\sim 5 \times 10^{-8}$  (60,89), but, it is common practice to use a higher  $p$  value threshold for follow-up study or replication. Balding (90) provides a

comprehensive discussion of the advantages and disadvantages of these methods pertaining to GWAS.

### 12.6.2 Validation and Replication Phase

Some investigators have recommended reanalysis of the original discovery phase GWAS data using a different genotype platform for validation, which has been termed *technical validation* (58). Technical validation allows detection of technical errors in genotyping that might give rise to spurious association signals or false positives, but given limitations of the resources available to investigator, it may not be feasible. The replication phase or follow-up study is one of the most challenging aspects of the GWAS and is required to control for false positives. Replication in an independent data set with similar genetic background and phenotype is warranted. Usually several hundreds or a few thousands of SNPs are tested in a replication set, depending on the threshold used for significant association  $p$  value. The statistical methods are the same as in the discovery phase, depending on the study design and type of phenotype.

## 12.7 ANALYSIS OF RARE VARIANTS USING NEW TECHNOLOGIES

Introduction of the HapMap project and large-scale GWAS studies were driven by the “common disease, common variant” (CVCD) hypothesis that was first introduced in the 1990s (50,91). The CDCV is based on the idea that the genetic component of common diseases is attributable in part to allelic variants that are present in more than 5% of the population. An extension of this hypothesis is that the same variants will be responsible for the disease across multiple populations (92). The early success of GWAS (age-related macular degeneration) seemed to support the theory that a large proportion of the genetic variants underlying complex disease could be explained by the CDCV. It is now becoming apparent that many common variants confer only a small portion of risk individually and also explain a small portion of the heritability of common complex diseases (93). While GWAS have been successful in many ways, identifying hundreds of variants for a large number of traits (<http://www.genome.gov/26525384>), there still remains a large proportion of heritability that has yet to be explained.

When the CDCV hypothesis was first introduced, it was not without contention (94). One of the strongest counter arguments was based on the hypothesis of “common disease, rare variant,” (CDRV) which is in essence the antithesis of the CDCV hypothesis (77,95). The rare variant hypothesis proposes that common complex diseases are due to the combined effect of multiple rare variants with moderate to low individual risk. Unlike CVCD, it is generally thought that owing to population history, these rare variants will be population specific (96). It is only recently, with the availability of affordable large-scale sequencing

technology and advances in analytical methods (discussed below), that scientists have gained the ability to address the role of CDRV in human disease. In reality, it is likely that the genetic basis of complex disease is somewhere between the two extremes, with multiple genes interacting together with a variety of common and rare variants and other genetic and environmental factors (97).

As new high-throughput, massively parallel sequencing technologies emerged in 2005, direct sequencing became commonly used to directly interrogate whole genomic sequences for association with disease without prior specification of SNPs currently available on commercial SNP chips (98). Such technologies overcome some of the shortcomings of GWAS methods, such as ascertainment bias in the set of currently available SNPs, and the ability to assay rare or private variants. In addition, greater flexibility exists in the search for variants other than SNPs, such as copy number variants, insertions or deletions or indels, inversions, and so on. Whole exome sequencing, in which only the sequence of exons are assayed, has been used to discover causal mutations in a number of Mendelian disorders such as Miller’s syndrome (99) and Hereditary Spastic Paraparesis (100). Because of the enormous number of variants introduced from new sequencing technologies and the small sample sizes typically present, new bioinformatic and statistical methods have been developed to reduce the dimensionality and improve the probability of detection of causal variants. Prior bioinformatic processing may include filtering by IBD methods if family data is present (101), or filtering based on the expected mode of inheritance (99). In addition, if only rare variants are desired, then common variants can be filtered out using dbSNP (102), and in addition, predicted functional variants (nonsense, missense, splice site variants, indels, frameshift mutations, etc.) can be discerned using tools such as SIFT and PolyPhen (102,103). Once likely non-functional variants have been filtered out, new statistical methods for summarizing the effect of multiple rare variants at a single gene can be applied. Some examples of these methods include the cohort allelic sums test method, which compares the number of individuals with mutations within a gene between cases and controls (104), the combined multivariate and collapsing (105), which collapses multiple rare variants in conjunction with common variants using multivariate analysis, methods that weight the counts of each variant using the estimated standard deviation of the total number of mutations (106,107), or a method that models these weights in a flexible Bayesian framework (108). A review of recent methods is given in reference (109). Whole-exome and whole-genome studies (in which the contribution of noncoding regions to disease can be assayed) are currently underway for complex (multifactorial) diseases. The next couple of years will show if these technologies can help to fill in the gaps from GWAS studies, termed *missing heritability* (93), and in identifying causal variants underlying multifactorial diseases. In addition, new sequencing technologies

offer opportunities for functional characterization studies such as gene expression profiling using next generation sequencing (110), epigenetic profiling (111), and in identifying somatic mutations occurring in cancer (112–114).

## 12.8 INTEGRATION OF GENETIC, GENOMIC, AND FUNCTIONAL DATA FOR ANALYSIS OF MULTIFACTORIAL DISEASES

Genes do not work in isolation, but instead work in concert to carry out complex biological functions (115). The field of “Systems Biology” is an emerging area of research that aims to study these complex interactions (116–118). Following the Central Dogma of molecular biology (DNA→RNA→Protein), the ability to integrate genetic data with other types of information (e.g. gene expression, protein interaction, etc.) is essential to our ability to understand the underlying complex etiology. A systems biology approach to complex diseases is possible in part due to the ever increasing amount of omics data (e.g. genomics, proteomics, metabolomics, etc.) that is becoming available in public databases, the scientific literature, and elsewhere. There are a wealth of methods that have been developed, or are being developed, that are designed to utilize this wealth of data to help prioritize and interpret results of genetic association studies. One of the most popular types of methods is *pathway analysis*, often referred to as *gene set analysis*, which can be broadly defined as methods that use preexisting information about SNPs, genes, transcripts, or other genomic information to interrogate subsets (e.g. pathways) of genomic variables as they relate to a complex trait or disease. These methods were first developed for genome-wide gene expression studies, but have recently been applied to GWAS, and will have great utility in sequencing-based studies. These methods typically examine test statistics to determine if the members of a group of genes are enriched for association with a trait (e.g. gene set enrichment analysis (119,120)), or to test if the group itself is associated with the trait (e.g. gene set ridge regression in association studies, (121,122)). For additional information on these methods, see references (123–129). Inclusion of prior network knowledge or de novo network discovery in conjunction with pathway methods has also been shown to further improve genomic data discoveries, with significant examples in cancer as exemplified in (130–132).

## 12.9 CONCLUSIONS

Genetic modeling is a challenging art and science. Advances in molecular technology, statistical methodology,<sup>6</sup> and increasing availability of large

samples allow many new investigations to be undertaken on unprecedented scales. Interpretation of the resulting findings remains both difficult and one of the more exciting challenges facing today’s biomedical researchers.

### Biographies

**Christine Duarte, PhD.** Dr Duarte is an assistant professor in the Department of Biostatistics at University of Alabama at Birmingham. Her current research focuses on developing statistical methods for applying systems biology approaches to high-dimensional genomic data analysis. Her research interests falls into three main areas: (1) prediction of complex traits and disease from high dimensional genomic data; (2) developing network models for decomposing genetic effects on complex traits into intermediate phenotypes; and (3) integrating cross-platform genomic data using network modeling to explain biological processes of interest such as disease etiology and treatment response.

**Laura Kelly Vaughan, PhD.** Dr Vaughan is an assistant professor in the Section on Statistical Genetics in the Department of Biostatistics at the University of Alabama at Birmingham. Her research interests include integrating biological knowledge into the statistical analysis of complex genomic data, pathway analysis, and reproducible research practices.

**T Mark Beasley, PhD.** Dr Beasley is an associate professor and has been a faculty member of the UAB Department of Biostatistics and the Section on Statistical Genetics (SSG) since 2001. Dr Beasley has published over 30 articles in the area of statistical methodology, focused in five major areas: (1) methodological problems in statistical genetics; (2) nonparametric statistics; (3) simulation studies; (4) the use of linear models; (5) longitudinal analysis, and (6) mediation analysis. He has also coauthored over 30 applied research articles in a variety of disciplines including education, psychology, medicine, genetics, and gerontology, pharmacology.

**Hemant K Tiwari, PhD.** Dr Tiwari is William “Student” Sealy Gosset Professor in Biostatistics and Interim Head of the Section on Statistical Genetics in the School of Public Health at the University of Alabama at Birmingham. His research interests include genetic linkage analysis, disequilibrium mapping, genome-wide association studies (GWAS), population genetics, structural variations in the genome, pharmacogenetics/pharmacogenomics, and bioinformatics. At present, he is involved in gene mapping studies of rheumatoid arthritis, SLE, cardiovascular diseases, and obesity-related traits.

### 13.1 INTRODUCTION

With the monumental scientific advances that have resulted from the Human Genome Project, the genetic composition of populations can now be examined in detail. Thousands of rare alleles are known to be disease-causing mutations and for most of these diseases (e.g. cystic fibrosis, Tay–Sachs, phenylketonuria (PKU), hemophilia A, and familial hypercholesterolemia), many different mutations are found within the same gene. In general, the frequencies of these rare disease alleles differ among populations as do the frequencies of common alleles (>1%), many of which are associated with common diseases such as Crohn's disease, diabetes, coronary disease, celiac disease, multiple sclerosis and macular degeneration. The principles of population genetics attempt to explain the genetic diversity in present populations and the changes in allele and genotype frequencies over time. Population genetic studies facilitate the identification of alleles associated with disease risk and provide insight into the effect of medical intervention on the population frequency of a disease. Allele and genotype frequencies depend on factors such as mating patterns, population size and distribution, mutation, migration, and selection. By making specific assumptions about these factors, the Hardy–Weinberg law, a fundamental principle of population genetics, provides a model for calculating genotype frequencies from allele frequencies for a random mating population in equilibrium.

### 13.2 HARDY–WEINBERG LAW

The allele frequencies at a locus can always be calculated from the genotype frequencies, but the converse is not necessarily true. The Hardy–Weinberg law states that for a single autosomal locus in a large population in which (1) mating takes place at random with respect to genotype, (2) allele frequencies are the same in males and females, and (3) mutation, selection, and migration are negligible, genotype frequencies can be calculated from

allele frequencies after one generation regardless of the allele and genotype frequencies in the initial population. This is not true for a single X-linked locus or for any set of loci considered jointly; for these loci, the establishment of this relationship between allele and genotype frequencies takes more than one generation.

#### 13.2.1 Autosomal Locus

Consider a locus with two alleles,  $A_1$  and  $A_2$ , and suppose the population frequencies of the three genotypes  $A_1A_1$ ,  $A_1A_2$ ,  $A_2A_2$  are  $p_{11}$ ,  $p_{12}$ ,  $p_{22}$ , respectively, where  $p_{11} + p_{12} + p_{22} = 1$ , then, in this initial population, the frequency of  $A_1$  is  $p_{11} + \frac{1}{2}p_{12}$  and the frequency of  $A_2$  is  $p_{22} + \frac{1}{2}p_{12}$ . Random mating is approximately equivalent to random union of gametes. Thus, random mating within this initial population results in the following genotype frequencies in the next generation:

$$\text{Frequency of } A_1A_1 = \left(p_{11} + \frac{1}{2}p_{12}\right)^2$$

$$\text{Frequency of } A_1A_2 = 2\left(p_{11} + \frac{1}{2}p_{12}\right)\left(p_{22} + \frac{1}{2}p_{12}\right)$$

$$\text{Frequency of } A_2A_2 = \left(p_{22} + \frac{1}{2}p_{12}\right)^2$$

The genotype frequencies in this second generation may be different from those in the first generation. However, calculation of the allele frequencies from the genotype frequencies in the second generation gives

$$\begin{aligned} \text{Frequency of } A_1 &= \left(p_{11} + \frac{1}{2}p_{12}\right)^2 + \left(p_{11} + \frac{1}{2}p_{12}\right)\left(p_{22} + \frac{1}{2}p_{12}\right) \\ &= p_{11}\left(p_{11} + p_{12} + p_{22}\right) + \frac{1}{2}p_{12}\left(p_{11} + p_{12} + p_{22}\right) \\ &= p_{11} + \frac{1}{2}p_{12} \end{aligned}$$

Similarly, the frequency of  $A_2$  is  $p_{22} + \frac{1}{2}p_{12}$ , which is equal to  $1 - (p_{11} + \frac{1}{2}p_{12})$ . These allele frequencies

are identical to those in the first generation. In other words, if the allele frequencies are  $p = p_{11} + \frac{1}{2}p_{12}$  and  $q = 1 - p = p_{22} + \frac{1}{2}p_{12}$ , then after one generation of random mating, the genotype frequencies are  $p^2$ ,  $2pq$ , and  $q^2$ . These frequencies are the Hardy–Weinberg proportions, and the population is said to be in Hardy–Weinberg equilibrium.

Table 13-1 presents a numerical example, in which the initial population comprises 20, 40, and 140 individuals with genotypes  $A_1A_1$ ,  $A_1A_2$ , and  $A_2A_2$ , respectively. The genotype frequencies are

$$\text{Frequency } A_1A_1 = p_{11} = 20/200 = 0.10$$

$$\text{Frequency } A_1A_2 = p_{12} = 40/200 = 0.20$$

$$\text{Frequency } A_2A_2 = p_{22} = 140/200 = 0.70$$

and, therefore, the allele frequencies are

$$\text{Frequency } A_1 = 0.10 + \frac{1}{2}(0.20) = 0.2$$

$$\text{Frequency } A_2 = 0.70 + \frac{1}{2}(0.20) = 0.8$$

Random union of gametes results in the following genotype frequencies in the next generation:

$$\text{Frequency } A_1A_1 = 0.2^2 = 0.04$$

$$\text{Frequency } A_1A_2 = 2(0.2)(0.8) = 0.32$$

$$\text{Frequency } A_2A_2 = 0.8^2 = 0.64$$

Note that these genotype frequencies are different from those in the initial population. To confirm that these results are correct, Table 13-1 shows the genotype frequencies in the offspring that result from each of the six possible mating types. For example, all the offspring of the mating  $A_1A_1 \times A_1A_1$  must be  $A_1A_1$ , while for the mating type  $A_1A_1 \times A_1A_2$ , each of the two offspring genotypes,  $A_1A_1$  and  $A_1A_2$ , has a probability of one half. (Table 13-1) Summing-up the columns in Table 13-1 gives the frequencies of each of the genotypes in the second generation. These frequencies are the same as those obtained by random union of gametes, and the allele frequencies calculated from these genotype frequencies are

$$\text{Frequency } A_1 = 0.04 + \frac{1}{2}(0.32) = 0.2$$

$$\text{Frequency } A_2 = 0.64 + \frac{1}{2}(0.32) = 0.8$$

Repeating these steps will give identical genotype and allele frequencies in the third generation to those in the second generation. Note that only the genotype frequencies change in the establishment of equilibrium; the allele frequencies in the initial population remain the same in subsequent generations.

The chi-square goodness-of-fit test may be used to determine whether the observed numbers of each genotype are significantly different from those expected under Hardy–Weinberg equilibrium. The total number of individuals is 200, so the expected numbers for the three genotypes are  $(0.2)^2 200 = 8$ ,  $2(0.2)(0.8) 200 = 64$ , and  $(0.8)^2 200 = 128$ , compared with the observed numbers of 20, 40, and 140. The test value is  $(20 - 8)^2/8 + (40 - 64)^2/64 + (140 - 128)^2/128 = 28$ . This value is compared to the chi-square distribution with one degree of freedom. (There are three classes, but the total number of individuals is known and also the allele frequencies are known. Thus, there is only one independent class and one degree of freedom.) In general, the number of degrees of freedom is equal to the number of genotypes minus the number of alleles. The 99.9th percentile of the chi-square distribution with one degree of freedom is 10.83.

Thus, the observed numbers of each genotype in the initial population are significantly different at the 1% level from those expected under Hardy–Weinberg equilibrium. However, after one generation of random mating, the observed and expected numbers are the same.

Calculation of allele frequencies from genotype frequencies is straightforward when all three genotypes are observable, but, in the case of recessive diseases, such as cystic fibrosis, only two phenotype classes are observed. However, if equilibrium is assumed, the frequency of affected individuals is  $q^2$ ; thus, the square root of this frequency is the frequency of the disease allele. The frequency of heterozygotes (carriers) is  $2(1 - q)q$ , and the proportion of carriers among unaffected individuals in the population is

$$[2(1 - q)q] / (1 - q^2) = 2q / (1 + q)$$

**TABLE 13-1** Table Establishment of Equilibrium in One Generation for an Autosomal Locus

	Mating Frequency	Offspring Genotype Frequencies		
		$A_1A_1$	$A_1A_2$	$A_2A_2$
$A_1A_1 \times A_1A_1$	$(0.1)^2$	$(0.1)^2$	0	0
$A_1A_1 \times A_1A_2$	$2(0.1)(0.2)$	$(0.1)(0.2)$	$(0.1)(0.2)$	0
$A_1A_1 \times A_2A_2$	$2(0.1)(0.7)$	0	$2(0.1)(0.7)$	0
$A_1A_2 \times A_1A_2$	$(0.2)^2$	$1/4(0.2)^2$	$1/2(0.2)^2$	$1/4(0.2)^2$
$A_1A_2 \times A_2A_2$	$2(0.2)(0.7)$	0	$(0.2)(0.7)$	$(0.2)(0.7)$
$A_2A_2 \times A_2A_2$	$(0.7)^2$	0	0	$(0.7)^2$
Total	1	0.04	0.32	.64

For example, in populations of European ancestry, the frequency of cystic fibrosis is estimated to be 1/2000; thus, the frequency of the abnormal allele is 0.022 and the normal allele is 0.978. The frequency of heterozygotes is therefore  $2 \times 0.022 \times 0.978$ , which is about 1/23. That is, approximately 4% of the populations are carriers, but less than 0.1% are affected. Several different mutations have been described in the cystic fibrosis gene. Each one of these is a disease allele; thus, the frequency of 0.022 is actually the sum of the frequencies of all the disease alleles in the cystic fibrosis gene.

The Hardy–Weinberg principle may be extended to more than two alleles. In general, for  $n$  alleles,  $A_1, A_2, \dots, A_n$ , with frequencies  $p_1, p_2, \dots, p_n$ , the genotype frequencies are  $p_i^2$  for homozygotes  $A_iA_i$  and  $2p_i p_j$  for heterozygotes  $A_iA_j$ . The heterozygosity value ( $H$ ) for a locus is the total frequency of heterozygotes, and it may be written as

$$H = \sum 2p_i p_j = 1 - \sum p_i^2$$

For two alleles, the maximum heterozygosity is 0.5, for five alleles it is 0.8, and for 10 alleles it is 0.9. In other words, for a locus to have a heterozygosity of 80%, it must have at least five alleles. (The maximum heterozygosity is reached when the alleles have equal frequencies.)

### Example

Suppose a locus has five alleles (designated 1, 2, 3, 4, 5) with frequencies 0.5, 0.3, 0.1, 0.08, 0.02. What are the genotype frequencies when Hardy–Weinberg equilibrium is established? What is the heterozygosity value ( $H$ ) at this locus?

With  $n$  alleles, there are  $n(n+1)/2$  genotypes. Thus, for five alleles there are 15 genotypes. The frequencies of the five homozygotes, 1–1, 2–2, 3–3, 4–4, 5–5, are 0.25, 0.09, 0.01, 0.0064, 0.0004, respectively. The frequencies of the 10 heterozygotes, 1–2, 1–3, 1–4, 1–5, 2–3, 2–4, 2–5, 3–4, 3–5, 4–5, are 0.3, 0.1, 0.08, 0.02, 0.06, 0.048, 0.012, 0.016, 0.004, 0.0032, respectively.

Heterozygosity ( $H$ )

$$= 1 - (0.25 + 0.09 + 0.01 + 0.0064 + 0.0004) \\ = 0.6432$$

## 13.2.2 X-Linked Locus

The genotype frequencies at a locus on the X chromosome differ in the two sexes because males have only one X chromosome, whereas females have two X chromosomes. Thus, in males the genotype frequency is equal to the allele frequency. For Hardy–Weinberg equilibrium, the allele frequencies in males must be equal to those in females. Suppose the frequency of the  $A_1$  allele is  $p_m$  in males and  $p_f$  in females in the first generation. By the principles of X-linked inheritance, the frequency of this allele in males in the second generation must be  $p_f$  because males get their X chromosomes from their mothers. By contrast, for females in the second generation the frequency of the  $A_1$  allele is  $\frac{1}{2}(p_m + p_f)$  because females

get one X chromosome from each parent. The difference between the male and female frequencies in this generation is  $p_f - \frac{1}{2}(p_m + p_f) = \frac{1}{2}(p_f - p_m)$ , which is one half of the difference in the first generation. Similarly, in the third generation, the male allele frequency is  $\frac{1}{2}(p_m + p_f)$ , while the female frequency is  $\frac{1}{2}p_m + \frac{3}{4}p_f$ , and the difference is  $\frac{1}{4}(p_f - p_m)$ . With each generation, the difference between the male and female frequencies becomes smaller, and equilibrium is reached when they are the same. The equilibrium allele frequency of  $A_1$  is equal to  $\frac{2}{3}p_f + \frac{1}{3}p_m$  in both sexes. Table 13-2 shows the approach to equilibrium for an X-linked locus when the initial allele frequencies are 0.33 in males and 0.57 in females. With each generation, the difference between the frequencies in males and females is reduced, and they approach the equilibrium frequency of  $\frac{2}{3}(0.33) + \frac{1}{3}(0.57) = 0.49$ . If the frequencies of the two alleles at the locus ( $A_1$  and  $A_2$ ) are  $p = \frac{1}{3}p_m + \frac{2}{3}p_f$  and  $q = 1 - p$ , the equilibrium genotype frequencies are  $p$  and  $q$  in males and  $p^2$ ,  $2pq$ , and  $q^2$  in females. Table 13-3 gives the frequency of each possible mating type and the expected offspring genotype frequencies for males and females. Summing-up these genotype frequencies shows that the equilibrium frequencies are maintained in the next generation (Table 13-3).

### Example

Suppose the frequency of an allele at an X-linked locus is 0.03 in males and 0.06 in females. What is the equilibrium allele frequency? Furthermore, suppose that this allele is responsible for a recessive trait. What are the equilibrium frequencies of this trait in males and females, and what is the frequency of heterozygous (carrier) females?

The equilibrium frequency of the allele is  $\frac{2}{3}(0.03) + \frac{1}{3}(0.06) = 0.05$ . Thus, the frequency of males with the trait is 0.05 and the frequency of females with the trait is  $(0.05)^2 = 0.0025$ . The frequency of carrier females is  $2(0.05)(0.95) = 0.095$ .

**TABLE 13-2** Approach to Equilibrium for a Locus on the X Chromosome

Generation	$p_m$	$p_f$
0	0.33	0.57
1	0.57	0.45
2	0.45	0.51
3	0.51	0.48
4	0.48	0.495
5	0.495	0.4875
6	0.4875	0.49125
7	0.49125	0.489375

$A_2A_2B_2B_2$	$g_{22}^2$	$p_2^2q_2^2$

### 13.2.3 Two Loci

Equilibrium is reached after one generation of random mating for a single autosomal locus and over several generations for an X-linked locus. However, the approach to equilibrium may be much longer for two loci considered jointly, and the number of generations depends on the recombination fraction. Suppose the first locus has alleles  $A_1$  and  $A_2$ , with frequencies  $p_1$  and  $p_2$ , and the second locus has alleles  $B_1$  and  $B_2$ , with frequencies  $q_1$  and  $q_2$ , respectively. The four possible gametes are  $A_1B_1$ ,  $A_1B_2$ ,  $A_2B_1$ ,  $A_2B_2$ ; let their frequencies in the population be  $g_{11}$ ,  $g_{12}$ ,  $g_{21}$ ,  $g_{22}$ , where  $p_1 = g_{11} + g_{12}$ ,  $p_2 = g_{21} + g_{22}$ ,  $q_1 = g_{11} + g_{21}$ , and  $q_2 = g_{12} + g_{22}$ . Allowing these gametes to unite at random gives the genotype frequencies in the next generation (Table 13-4). Now consider the gametic output of this population. In doing so, we must take into account the fact that the frequency of gametes produced by the double heterozygote ( $A_1A_2B_1B_2$ ) depends on the recombination fraction,  $\theta$  (Table 13-4). If the phase is  $A_1B_1/A_2B_2$ , then  $A_1B_1$  and  $A_2B_2$  are nonrecombinants, and  $A_1B_2$  and  $A_2B_1$  are recombinants. Conversely, if phase is  $A_1B_2/A_2B_1$ , then  $A_1B_2$  and  $A_2B_1$  are nonrecombinants, and  $A_1B_1$  and  $A_2B_2$  are recombinants. Therefore, the frequency of  $A_1B_1$  gametes from double heterozygotes

is  $g_{11}g_{22}(1 - \theta) + g_{12}g_{21}\theta$ . In addition, all the gametes produced by individuals with the genotype  $A_1A_1B_1B_1$ , and one half of those produced by individuals with the genotypes  $A_1A_1B_1B_2$  and  $A_1A_2B_1B_1$  will be  $A_1B_1$ . Thus, the total frequency of  $A_1B_1$  gametes in this generation is  $g_{11}^2 + g_{11}g_{12} + g_{11}g_{21} + g_{11}g_{22}(1 - \theta) + g_{12}g_{21}\theta$ , which may be written as  $g_{11} - \theta D$ , where  $D = g_{11}g_{22} - g_{12}g_{21}$ .  $D$  is called the coefficient of linkage disequilibrium (LD) and is a measure of allelic association. Similar calculations may be done for each of the gametic types, and the frequencies obtained are  $g_{12} + \theta D$ ,  $g_{21} + \theta D$ , and  $g_{22} - \theta D$  for  $A_1B_2$ ,  $A_2B_1$ , and  $A_2B_2$ , respectively.

If the loci are unlinked,  $\theta = 1/2$ , and the change in gametic frequency from one generation to the next is  $1/2D$ . For linked loci the change is  $\theta D$ . Thus, the more closely two loci are linked, the slower is the approach to equilibrium. The coefficient of LD after  $t$  generations may be written as

$$D_t = (1 - \theta) D_{t-1} = (1 - \theta)^t D_0$$

which approaches zero as  $t$  tends to infinity.

At equilibrium,  $D$  is equal to zero and the genotype and gametic frequencies are products of the allele frequencies (see Table 13-4). The gametic frequencies may be written as  $g_{11} = p_1q_1 + D$ ,  $g_{12} = p_1q_2 - D$ ,  $g_{21} = p_2q_1 - D$ , and  $g_{22} = p_2q_2 + D$ . Each of these gametic frequencies must be greater than or equal to zero. Thus,  $D$  must be greater than or equal to both  $-p_1q_1$  and  $-p_2q_2$ , and  $D$  must be less than or equal to both  $p_1q_2$  and  $p_2q_1$ . These results may be written as

$$D_{\min} = \max(-p_1q_1, -p_2q_2)$$

$$D_{\max} = \min(p_1q_2, p_2q_1)$$

For two loci each with two alleles,  $D$  must lie between  $-0.25$  and  $0.25$ , and it can reach these extreme values only if the frequencies of the four alleles are  $0.5$ . Thus, the value of  $D$  is dependent on allele frequencies, meaning that  $D$  values for different pairs of loci are not comparable. The value of the standardized measure,  $D' = D/D_{\text{extreme}}$ , where  $D_{\text{extreme}} = -D_{\min}$  if  $D < 0$  and  $D_{\max}$  if  $D > 0$ , is less dependent on the allele frequencies and lies between  $-1$  and  $1$ .

The statistic,  $\delta$ , is another measure of LD that is useful for estimating the location of a disease locus if a single mutation is likely. The formula is

$$\delta = (p_D - p_N) / (1 - p_N)$$

where  $p_D$  is the frequency of the associated allele on disease chromosomes and  $p_N$  is the frequency of this allele on normal chromosomes. This value represents an estimate of the proportion of disease chromosomes bearing the original associated allele. If there is a single mutation, the proportion of chromosomes carrying this mutation is the same for all marker loci, so differences in  $\delta$  across loci should largely represent effects of recombination. Thus,  $\delta$  can be used to determine the most likely location of the disease locus among a set of tightly linked marker loci.

The effectiveness of LD in locating disease mutations was demonstrated with the identification of the cystic fibrosis  $\Delta F508$  mutation in 1989. Over the next decade, it was used successfully in the identification of ethnic-specific disease mutations in the Ashkenazi Jewish, Finnish, Acadian, Roma, and other isolated and endogamous populations.

Note that LD is one possible explanation for association between a phenotype and a marker allele in a population. In this case, the disease locus is tightly linked to the marker locus. However, population association does not necessarily mean tight linkage, and vice versa. Other possible reasons for association are pleiotropy (multiple effects of the same gene), such as the association between stomach cancer and the A allele of the ABO blood group and departures from random mating due to events such as racial admixture, stratification, inbreeding, and assortative mating.

### Examples

1. Suppose the frequencies of the gametes  $A_1B_1$ ,  $A_1B_2$ ,  $A_2B_1$ ,  $A_2B_2$  are 0.5, 0.1, 0.3, 0.1, respectively. What is the value of  $D$  after one generation of random mating if (1) the two loci are unlinked and (2) the recombination fraction between the two loci is 0.01?

The value of  $D$  in the original population is  $(0.5)(0.1) - (0.1)(0.3) = 0.02$ . After one generation,  $D = (1 - 0.5)(0.02) = 0.01$  if the two loci are unlinked, and  $D = (1 - 0.01)(0.02) = 0.0198$  if the recombination fraction is 0.01.

2. How many generations are required for the value of  $D$  to be one-half its initial value?

$D_t/D_0 = (1 - \theta)^t = 1/2$ ; therefore,  $t = \log(1/2)/\log(1 - \theta)$ . Thus, for  $\theta$  equal to 0.3, 0.1, 0.01, and 0.001, the numbers of generations required are approximately 2, 7, 69, and 693, respectively. Note that for unlinked loci,  $D$  is halved in one generation as seen in the first example.

## 13.3 FACTORS THAT AFFECT HARDY-WEINBERG EQUILIBRIUM

The assumption of a large, random mating population is fundamental to Hardy-Weinberg equilibrium. If mating is not at random, the allele frequencies at a locus (say,  $p$

and  $q$ ) in the population do not change from one generation to the next, but the genotype frequencies are not  $p^2$ ,  $2pq$ , and  $q^2$ . Evolutionary forces such as random genetic drift, mutation, selection, and migration, however, will change allele frequencies (and consequently genotype frequencies) from one generation to the next.

### 13.3.1 Factors that Affect Genotype Frequencies but Not Allele Frequencies

Random mating has been assumed so far in all the derivations. If gametes do not unite at random, the genotype frequencies are not in Hardy-Weinberg proportions and cannot be derived simply from allele frequencies. Consanguinity (inbreeding), assortative mating, and stratification (e.g. ethnic subgroups within a population) are examples of nonrandom mating. In these situations, the frequency of homozygotes is increased at the expense of heterozygotes, and the genotype frequencies may be significantly different from Hardy-Weinberg expectations. However, allele frequencies do not change.

**13.3.1.1 Consanguinity and Inbreeding.** Individuals who are related genetically are termed consanguineous, and the offspring of mating between such individuals are said to be inbred. Inbreeding increases the frequency of homozygous genotypes and decreases the frequency of heterozygous genotypes in the population. The offspring of consanguineous marriages have an increased risk over that of the general population of having recessive disorders. The increase in risk depends on the population frequency of the disease allele and the degree of relationship between the parents. In cultures in which uncle-niece and first- and second-cousin marriages are encouraged, recessive disorders that are rare in most randomly mating populations may be relatively common. The coefficient of inbreeding ( $F$ ) for a child of a consanguineous marriage is the probability that the child receives two alleles at a given locus that are both from the same ancestor and are, thus, identical by descent (autozygous). For example, half first cousins share a grandparent in common. The probability that a child of half first cousins is homozygous by descent at a locus is  $F = (1/2)^5 = 1/32$ . In general, for autosomal loci, the inbreeding coefficient for an individual is  $F = (1/2)^{n_1 + n_2 + 1}$ , where  $n_1$  and  $n_2$  are the numbers of generations separating the individuals in the consanguineous mating from their common ancestor. (This formula assumes that the common ancestor is not inbred.) Half first cousins are separated from their common grandparent by two generations. Thus, the exponent is  $2 + 2 + 1 = 5$ . Table 13-5 gives the estimated proportion of alleles shared by consanguineous individuals that are identical by descent as well as the coefficient of inbreeding for the offspring of these consanguineous matings (Table 13-5). If a child is inbred through more than one line of descent, the total coefficient of inbreeding is the sum of each of the separate coefficients. For example, first cousins are related through two grandparents. Thus,

**TABLE 13-5** Proportion of Alleles Shared by Related Individuals that Are Identical by Descent and the Inbreeding Coefficient ( $F$ ) in the Offspring of Various Types of Consanguineous Mating

Type of Mating	Proportion of Shared Alleles	$F$
Parent–offspring	1/2	1/4
Brother–sister	1/2	1/4
Half sibs	1/4	1/8
Uncle–niece, aunt–nephew	1/4	1/8
First cousins	1/8	1/16
Double first cousins	1/4	1/8
Half first cousins	1/16	1/32
First cousins once removed	1/16	1/32
Second cousins	1/32	1/64
Second cousins once removed	1/64	1/128
Third cousins	1/128	1/256

the inbreeding coefficient for the offspring of first cousins is  $F = (\frac{1}{2})^5 + (\frac{1}{2})^5 = (\frac{1}{2})^4 = \frac{1}{16}$ . The coefficient of inbreeding is also an estimate of the proportion of loci at which an individual is autozygous.

The coefficient of inbreeding for X-linked loci depends on the number of males in the lines of descent and is always zero for male offspring, because they have only one X chromosome. In order to calculate the inbreeding coefficient for daughters of first cousins, four possibilities need to be considered for the first cousins: their fathers are brothers, their mothers are sisters, the father of the male cousin and the mother of the female cousin are siblings, or vice versa. If the fathers are brothers, the first cousins cannot share any X-linked alleles in common because the male first cousin did not inherit an X chromosome from his father. Thus, female offspring of this type of first-cousin mating are not inbred for X-linked loci and have an inbreeding coefficient of zero. Similarly, if the first cousins are offspring of a brother and a sister with the father being the son of the brother and the mother being the daughter of the sister, the inbreeding coefficient for their daughters is zero because the first cousins cannot share any X-linked alleles in common. On the other hand, if the mothers of the first cousins are sisters, then the inbreeding coefficient for X-linked loci in their daughters is greater than that for autosomal loci because a male transmits the X chromosome he received from his mother to all his daughters. Thus, the inbreeding coefficient in this situation is  $(\frac{1}{2})^3 + (\frac{1}{2})^4 = \frac{3}{16}$ . The fourth possibility is that the first cousins are offspring of a brother and sister, with the sister being the mother of the male and the brother being the father of the female. In this case, the inbreeding coefficient for X-linked loci in female offspring is  $(\frac{1}{2})^3 = \frac{1}{8}$ .

Genotype frequencies in inbred populations cannot be calculated from the allele frequencies alone, but they

can be obtained if the average inbreeding coefficient in the population is known. The amount of inbreeding in the population may be measured in terms of the decrease in heterozygosity relative to a random mating population. If the allele frequencies at a locus are  $p$  and  $q$ , then under random mating the frequency of heterozygotes is  $2pq$ . Suppose the frequency of heterozygotes in the inbred population is  $H$ . Then the inbreeding coefficient for the population is  $F = (2pq - H)/2pq$ . Therefore,  $H = 2pq - 2pqF$ . The frequencies of the two types of homozygotes in the inbred population can then be calculated to be  $p^2 + pqF$  and  $q^2 + pqF$ . If the inbreeding coefficient is zero (i.e. random mating), the genotype frequencies are those expected for Hardy–Weinberg equilibrium. On the other hand, if there is complete inbreeding ( $F = 1$ ), the frequency of heterozygotes is zero, and the population consists only of homozygotes with frequencies of  $p$  and  $q$ . However, note that the allele frequencies will not change from one generation to the next, regardless of the value of the inbreeding coefficient in the population.

### Example

Suppose the frequency of an autosomal recessive disease is 1/40,000 in the general population. What is the expected frequency of the disease among the offspring of first cousins?

The frequency of the deleterious allele is 1/200, the square root of the frequency of the disease. The inbreeding coefficient for offspring of first-cousin marriages is 1/16. Thus, the frequency of the disease among the offspring of first cousins is  $1/40,000 + (199/200)(1/200)(1/16) = 1/2977$ .

**13.3.1.2 Assortative Mating.** Assortative mating is the tendency for people to choose mates who are more similar (positive) or dissimilar (negative) to themselves in phenotype characteristics than would be expected by chance. If these characteristics are genetically determined, positive assortative mating may increase homozygosity in the population. An important difference between inbreeding and positive assortative mating is that inbreeding affects all loci, while assortative mating affects only those that play a role in the phenotype characteristics that are similar. Clinical examples of positive assortative mating are those between individuals who are profoundly hearing impaired or blind, which in some cases may be attributable to the same genotypes.

**13.3.1.3 Stratification.** A stratified population is one in which mating occurs within subgroups, and thus mating is not random in the population (even though random mating may occur in each subgroup). Suppose there are two subgroups ( $A_1$  and  $A_2$ ) with allele frequencies of  $p_1$  and  $q_1$ , and  $p_2$  and  $q_2$ . Then the frequency of heterozygotes in the combined population ( $A_1 + A_2$ ) is  $p_1q_1 + p_2q_2$ . If there was random mating in  $A_1 + A_2$ , then after one generation the frequency of heterozygotes would be  $p_1q_1 + p_2q_2 + \frac{1}{2}(p_1 - p_2)^2$ , which is always

greater than  $p_1q_1 + p_2q_2$ , while the decrease in each of the two homozygote frequencies is  $1/4(p_1 - p_2)^2$ . Thus, if  $A_1$  and  $A_2$  remain as separate subgroups, the frequency of heterozygotes in the combined population will always be lower (and the frequency of homozygotes greater) than expected under Hardy–Weinberg equilibrium.

### 13.3.2 Factors That Affect Allele Frequencies

Evolutionary forces such as random genetic drift, mutation, selection, and migration change the allele frequencies in a population. Important examples of each of these forces have been documented in human populations, and their effects are becoming better understood as knowledge of the genetic structure of populations at the DNA level increases.

**13.3.2.1 Random Genetic Drift.** The Hardy–Weinberg principle assumes that population size is large, and this assumption is probably valid for many present-day populations. However, if the population size is small, allele frequencies may change from one generation to the next by chance alone. This change is a consequence of sampling in small populations and is called random genetic drift. The sample is the set of gametes that contributes to the next generation. Suppose this sample consists of  $2N$  gametes ( $N$  individuals) and consider a locus with two alleles,  $A_1$  and  $A_2$ . The  $2N+1$  possible values of the frequency of  $A_1$  are

$$0, 1/2N, 2/2N, 3/2N, \dots, (2N-1)/2N, 2N/2N$$

The probability that the number of  $A_1$  alleles in the population is  $k$  ( $0 \leq k \leq 2N$ ) depends on the population size and the frequencies,  $p$  and  $q$ , of  $A_1$  and  $A_2$ , respectively, in the previous generation. It may be written as

$$Pr(k) = \binom{2N}{k} p^k q^{2N-k}$$

Thus, if  $N$  and  $p$  are known, the probability of a particular frequency of  $A_1$  in the next generation may be calculated. For example, if  $N=50$  and  $p=0.5$ , the probability that the frequency of  $A_1$  in the next generation is less than 0.4 or greater than 0.6 is 0.023, while the probability that it is between 0.45 and 0.55 is 0.682. The probability that  $A_1$  will either be lost or become fixed in the population in the next generation is extremely small, but is greater than zero. If  $N=50$  and  $p=0.01$ , the probability that  $A_1$  will be lost in the next generation is 0.37, and the probability that it will have a frequency of greater than 0.05 is 0.002. The precise change in allele frequency from one generation to the next cannot be predicted because drift is a random process. However, over a number of generations, drift can lead to the loss of some alleles from the population, with others becoming fixed. If a large number of populations are considered, the average behavior of allele

frequencies can be predicted. The probability that a new allele in a population will eventually become fixed is  $1/2N$ , the frequency of the allele in the population at the time it arose. If the allele is to become fixed in the population, the average time to fixation is approximately  $4N$  generations. After a large enough number of generations of random genetic drift, every allele in a population can be traced back to a single allele in the initial ancestral population. All other alleles in the initial population will have been lost. This concept is known as coalescence, and it has been used to model DNA sequence variation in populations.

Random genetic drift in a population is similar to inbreeding and stratification, in that its effect on the population is a reduction in the number of heterozygotes and an increase in the number of homozygotes. When the population size is drastically reduced (a bottleneck), the genetic drift is known as a founder effect. Examples of this effect (e.g. new colonization by a small subset of a population or environmental disasters such as plague and famine) abound in history. Founder effect is likely to explain the relatively high frequency of certain diseases in some ethnic groups (e.g. Tay–Sachs disease in the Ashkenazi Jewish population).

#### Example

Suppose a new mutation arises in a population of size 500. What is the probability that this allele will be lost in the next generation? What is the probability that it will eventually become fixed in the population?

The total number of gametes in the population is 1000. Thus, the frequency of the new allele is 0.001, and the probability that it will be lost in the next generation is  $[1000!/(0!)(999!)](0.999)^{1000} (0.001)^0 = 0.37$ . The probability that this new allele will eventually become fixed in the population is  $1/1000$ .

**13.3.2.2 Mutation.** When mutations occur in the germ cells, they may be passed on to the next generation. The change in the DNA may be a single nucleotide substitution or it may involve many nucleotides, such as in the case of an insertion or deletion. Many hemoglobinopathies are due to point mutations that cause the replacement of an amino acid (missense) and consequently an abnormal protein product. The most common mutation causing Tay–Sachs disease is a 4-base-pair (bp) insertion (frameshift), while the  $\Delta F508$  mutation in the cystic fibrosis gene is a 3-bp deletion.

The source of genetic variation in a population is mutation. Mutation rates in humans have been estimated to be of the order  $10^{-4}$ – $10^{-6}$  per gene per generation. The rate of nucleotide substitutions is estimated to be 1 in  $10^8$  per generation, implying that 30 nucleotide mutations would be expected in each human gamete.

Most new mutations are lost due to chance. However, new mutations arise in each generation, and some become

**TABLE 13-6** Selection against the  $A_2A_2$  Genotype at an Autosomal Locus

Genotype	$A_1A_1$	$A_1A_2$	$A_2A_2$
Frequency before selection	$p^2$	$2pq$	$q^2$
Relative fitness	1	1	$1-s$
Frequency after selection	$p^2$	$2pq$	$q^2(1-s)$
After one generation of selection			
Frequency $A_1 = (p^2 + pq)/[p^2 + 2pq + q^2(1-s)] = p/(1-sq^2)$			
Frequency $A_2 = [pq + (1-s)q^2]/(1-sq^2)$			
If $s = 1$ (i.e. complete selection against the $A_2A_2$ genotype), then			
After one generation of selection			
Frequency $A_1 = (p^2 + pq)/(p^2 + 2pq) = 1/(1+q)$			
Frequency $A_2 = pq/(p^2 + 2pq) = q/(1+q)$			
After $t$ generations of selection			
Frequency $A_1 = [1 + (t-1)q]/(1+q)$			
Frequency $A_2 = q/(1+q)$			

established in the population. Suppose  $\mu$  is the mutation rate from  $A_1$  to  $A_2$  per generation. If the frequencies of  $A_1$  and  $A_2$  are  $p_t$  and  $q_t$ , respectively, in generation  $t$ , then in the  $(t+1)$ th generation the frequency of  $A_2$  is

$$q_{t+1} = q_t + \mu p_t = q_t + \mu(1 - q_t) = \mu + (1 - \mu)q_t$$

assuming no back mutation.

Similarly,  $q_t = \mu + (1 - \mu)q_{t-1}$ ,  $q_{t-1} = \mu + (1 - \mu)q_{t-2}$ , and so forth. By substitution,  $q_t$  may be written in terms of  $q_0$ , the frequency of  $A_2$  in the initial generation:

$$q_t = 1 - (1 - \mu)^t(1 - q_0)$$

$$\text{or } (1 - \mu)^t = (1 - q_t)/(1 - q_0) = p_t/p_0$$

Because  $\mu$  is very small,  $(1 - \mu)^t$  is approximately equal to  $e^{-t\mu}$ . Thus, the number of generations required to change the frequency of  $A_2$  from  $q_0$  to  $q_t$  is inversely proportional to the mutation rate. Also note that as  $t$  gets larger and larger,  $q_t$  gets closer and closer to 1. In other words, if mutation from  $A_1$  to  $A_2$  is the only force acting to change the allele frequencies, then  $A_2$  will eventually become fixed in the population. The change in allele frequency from one generation to the next is  $q_{t+1} - q_t = \mu(1 - q_t)$ , meaning that the change in allele frequency is greater for smaller frequencies of  $A_2$ .

So far we have considered mutation in only one direction. Now suppose the mutation rate from  $A_1$  to  $A_2$  is  $\mu$  and the reverse rate from  $A_2$  to  $A_1$  is  $\nu$ . Then the change in the frequency of  $A_2$  per generation is  $\mu p - \nu q$ , and equilibrium is reached when this change is equal to zero. Thus, the equilibrium frequencies are  $p = \nu/(\mu + \nu)$  and  $q = \mu/(\mu + \nu)$ . This equilibrium is stable, meaning that if the frequencies are disturbed, they will eventually return to their equilibrium values as long as no other forces are affecting them.

Mutation rates have been estimated for a number of autosomal dominant disorders, such as neurofibromatosis

type I, which has the high rate of  $10^{-4}$ , and tuberous sclerosis, with a rate of about  $10^{-5}$ . Some of these disorders (e.g. achondroplasia, for which the mutation rate is estimated to be  $10^{-5}$ ) have reduced fitness, which is discussed in the next section.

### Examples

1. How many generations will be required to change the frequency of  $A_2$  (a) from 0.1 to 0.2, (b) from 0.8 to 0.9, if the mutation rate from  $A_1$  to  $A_2$  is  $10^{-4}$ ?

The number of generations is

$$\begin{aligned} t &= 1/\mu [\ln(1 - q_0) - \ln(1 - q_t)] \\ &= 1/\mu [\ln(0.9) - \ln(0.8)] \\ &= 1/\mu (0.1178) \end{aligned}$$

Therefore, for a mutation rate of  $10^{-4}$ , 1178 generations are required, whereas for a mutation rate of  $10^{-5}$ , 11,780 generations are required to change the frequency of  $A_2$  from 0.1 to 0.2. On the other hand, to change the frequency from 0.8 to 0.9 requires 6932 generations if the mutation rate is  $10^{-4}$  and 69,315 generations if the mutation rate is  $10^{-5}$ .

2. Suppose the mutation rate from  $A_1$  to  $A_2$  is  $10^{-4}$  and the reverse rate is  $10^{-5}$ . What is the equilibrium frequency of  $A_1$ ?

The equilibrium frequency of  $A_1$  is  $10^{-5}/(10^{-4} + 10^{-5}) = 0.091$ . However, to reach this equilibrium frequency may take tens of thousands of generations, depending on the initial allele frequencies.

**13.3.2.3 Selection.** The fitness of an individual is defined as an ability to survive and reproduce. The process by which the frequencies of genotypes in individuals with greater fitness increase in the population is natural selection. It acts to decrease the frequencies of the less-fit genotypes. The relative fitness is defined as  $1 - s$ , where  $s$  is the selection coefficient against the deleterious genotype. Thus, the most-fit genotype has a relative fitness of 1 (and a selection coefficient of 0).

Consider the situation where there are three genotypes,  $A_1A_1$ ,  $A_1A_2$ ,  $A_2A_2$ , at a locus with relative fitnesses of 1, 1,  $1 - s$ , respectively. That is, there is selection against the  $A_2A_2$  homozygote. (If  $s = 1$ , the selection is complete, meaning that individuals with the  $A_2A_2$  genotype do not reproduce.) Table 13-6 shows the change in allele frequencies from one generation to the next. In the case in which  $s = 1$ , the frequencies after  $t$  generations can be written in terms of the initial allele frequencies (Table 13-6). Substituting in the formula given in Table 13-6 shows that when the  $A_2A_2$  homozygote does not reproduce, the number of generations required to reduce the frequency of  $A_2$  to one half its initial value is equal to the reciprocal of its initial value. Thus, if the frequency of  $A_2$  is 0.01, it will take 100 generations of complete selection against the  $A_2A_2$  homozygote to reduce the frequency of  $A_2$  to 0.005. In other words, lack of reproduction of individuals with a rare recessive disease does not lead to a

**TABLE 13-7** Selection Favoring the Heterozygous Genotype at an Autosomal Locus

Genotype	$A_1A_1$	$A_1A_2$	$A_2A_2$
Frequency before selection	$p^2$	$2pq$	$q^2$
Relative fitness	$1-s_1$	1	$1-s_2$
Frequency after selection	$p^2(1-s_1)$	$2pq$	$q^2(1-s_2)$
After one generation of selection			
Frequency $A_1 = (p-s_1p^2)/(1-s_1p^2-s_2q^2)$			
Frequency $A_2 = (q-s_2q^2)/(1-s_1p^2-s_2q^2)$			
The change in the frequency of $A_2$ from one generation to the next is $pq(s_1p-s_2q)/(1-s_1p^2-s_2q^2)$ . Equating this quantity to zero gives the equilibrium allele frequencies, which are			
Frequency $A_1 = s_2/(s_1+s_2)$			
Frequency $A_2 = s_1/(s_1+s_2)$			

rapid reduction in the frequency of the deleterious allele from one generation to the next.

Now consider the situation in which there is partial selection against the  $A_2A_2$  genotype. The allele frequencies after  $t$  generations cannot be written in terms of the initial frequencies, but the decrease in the frequency of the  $A_2$  allele from one generation to the next can be calculated. This decrease is equal to  $sq^2(1-q)/(1-sq^2)$ , and the number of generations required to change the frequency of  $A_2$  from its initial value to a new value can be approximated. For example, if  $s=0.001$  and the initial frequency of  $A_2$  is 0.01, more than 100,000 generations will be required to reduce the frequency to 0.005. This example makes the point that even if the selective disadvantage of a genotype is very small, the allele frequencies in the population will gradually change. For the same selection coefficient ( $s=0.001$ ), 11,665 generations are required to reduce the frequency of  $A_2$  from 0.7 to 0.1. If there is selection against the heterozygous genotype ( $A_1A_2$ ) as well as the  $A_2A_2$  genotype, with  $s=0.001$  for  $A_2A_2$  and  $s=0.0005$  for  $A_1A_2$ , then 6156 generations are required to reduce the frequency of  $A_2$  from 0.7 to 0.1.

In the case in which there is selection favoring the heterozygote over both homozygotes, an equilibrium state is reached for the allele frequencies. Table 13-7 shows the change in allele frequencies from one generation to the next. At equilibrium,  $s_1p = s_2q$ , so that  $p = s_2/(s_1 + s_2)$  and  $q = s_1/(s_1 + s_2)$  (Table 13-7).

This equilibrium is stable and is called a balanced polymorphism. This type of selection is known as overdominance. If, on the other hand, selection is against the heterozygote, the equilibrium is unstable, and the selection is known as underdominance. The equilibrium frequencies are the same, but if a disturbance occurs such that  $q > s_1/(s_1 + s_2)$ ,  $q$  will increase further rather than returning to its equilibrium value. The reverse is also true, so eventually one allele or the other will be eliminated.

Let us now consider a balance between mutation and selection. Suppose the mutation rate from  $A_1$  to  $A_2$  is  $\mu$ , and the relative fitnesses of the genotypes  $A_1A_1$ ,  $A_1A_2$ ,

**TABLE 13-8** X-Linked Locus: Selection against the  $A_2A_2$  Genotype in Females and the  $A_2$  Genotype in Males

Females			
Genotype	$A_1A_1$	$A_1A_2$	$A_2A_2$
Frequency before selection	$p^2$	$2pq$	$q^2$
Relative fitness	1	1	$1-s$
Frequency after selection	$p^2$	$2pq$	$q^2(1-s)$
Males			
Genotype	$A_1$	$A_2$	
Frequency before selection	$p$	$q$	
Relative fitness	1	$1-s$	
Frequency after selection	$p$	$q(1-s)$	
After one generation of selection in males			
Frequency $A_1 = p/(1-sq)$			
Frequency $A_2 = (q-sq)/(1-sq)$			

$A_2A_2$ , are 1, 1,  $1-s$ , respectively. As shown in Table 13-6, the frequency of  $A_1$  after selection is  $p/(1-sq^2)$ . Thus, the increase in frequency of  $A_2$  due to mutation from  $A_1$  to  $A_2$  is  $\mu p/(1-sq^2)$ , while the decrease due to selection is  $sq^2(1-q)/(1-sq^2)$ . At equilibrium,  $\mu p/(1-sq^2) = sq^2(1-q)/(1-sq^2)$ , which simplifies to  $q = \sqrt{\mu/s}$ . This equilibrium is stable and  $q = \sqrt{\mu}$  when  $s=1$ . Thus, for a lethal recessive disease and a mutation rate of  $10^{-6}$ , the equilibrium frequency of the deleterious allele is 1/1000.

In the case of a deleterious dominant phenotype, the fitness of both the homozygote and the heterozygote is reduced. With selection coefficients of  $1-s$ ,  $1-s$ , 1, the increase in the frequency of  $A_1$  due to mutation is equal to the decrease due to selection when  $q = \mu/s$ , which reduces to  $q = \mu$  for  $s=1$ . If individuals with a dominant disease do not reproduce, the frequency of the deleterious allele in the next generation is equal to the mutation rate. Examples of such disorders are atelosteogenesis and thanatophoric dysplasia, which are both lethal forms of short-limbed dwarfism. In the case of achondroplasia, fitness is not zero, but it is considerably lower than one, and is estimated to be about 0.2. Thus, the equilibrium frequency of the deleterious allele is  $10^{-5}/0.8 = 1.25 \times 10^{-5}$ , or slightly higher than the mutation rate.

Selection against genotypes at loci on the X chromosome needs to be tabulated separately for males and females because males have only one allele at an X-linked locus. Table 13-8 shows the case in which the  $A_2A_2$  genotype and the  $A_2$  genotype are selected against in females and males, respectively. The decrease in frequency of  $A_2$  due to reduced fitness in females is extremely small compared with the decrease due to reduced fitness in males. Thus, we will only consider males (Table 13-8). The loss of  $A_2$  alleles is equal to  $sq(1-q)/(1-sq)$ , which is  $q$  if  $s=1$ . In other words, if selection is complete, all male  $A_2$  alleles are lost in each generation. Because males have only one allele and females have two, this loss represents one third of the  $A_2$  alleles in the population. If

the mutation rate from  $A_1$  to  $A_2$  is  $\mu$ , the increase in frequency of  $A_2$  due to mutation in males is  $\mu p/(1-sq)$ . But mutation in males represents only one third of the mutations that are occurring in the population. Thus, increase in frequency due to mutation balances decrease due to selection when  $3\mu p/(1-sq) = sq(1-q)/(1-sq)$ , which reduces to  $q = 3\mu/s$ . For an X-linked recessive lethal,  $s = 1$ , and  $\mu = q/3$ . In other words, one third of the deleterious alleles in the population, and, thus, one third of cases of diseases such as Duchenne muscular dystrophy, are new mutations. In less severe X-linked disorders, the proportion of cases that are new mutations is not as high; for example, the relative fitness of individuals with hemophilia A is about 70%. Therefore, the proportion of new mutations is  $0.3q/3$ , meaning that about 10% of cases are new mutations. Of course, during the initial years of the AIDS epidemic when blood was not being screened for HIV, the relative fitness of hemophiliacs was considerably lower than 70%. The effect of this transient reduction on the frequency of hemophilia A will be seen in future generations.

### Example

Suppose the relative fitnesses of the genotypes  $A_1A_1$ ,  $A_1A_2$ ,  $A_2A_2$  are 0.8, 1, 0.1, respectively. What are the equilibrium frequencies of the two alleles?

The heterozygote has a selective advantage in this population. At equilibrium, the frequencies of  $A_1$  and  $A_2$  are  $0.9/1.1 = 0.82$  and  $0.2/1.1 = 0.18$ , respectively. Even though selection against the  $A_2A_2$  homozygote is quite extreme, the equilibrium frequency of  $A_2$  is relatively high because of overdominance. If the relative fitnesses were 0.9, 1, 0.7, the frequencies of  $A_1$  and  $A_2$  would be 0.75 and 0.25, respectively.

**13.3.2.4 Migration (Gene Flow).** Migration introduces alleles into the population and, like mutation, increases heterozygosity. In general, migration rates are higher than mutation rates, so migration is more effective than mutation in counterbalancing the effects of genetic drift.

Comparison of alleles in different ethnic groups demonstrates the contribution of gene flow to the current population gene pools. For example, the most common mutations in phenylalanine hydroxylase that cause PKU are likely to be of Celtic origin. These same mutations have been found in many different populations throughout the world, reflecting the migrations of the Celts.

## 13.4 APPLICATIONS IN POPULATION GENETICS

The evolutionary forces that govern the frequencies of genotypes and alleles provide us with the tools to understand the genetic structure of populations. Such tools can help deduce why some disease mutations are relatively common in some ethnic groups, but not in others. Ethnic variation in allele frequencies is found throughout the

genome, and by examining this genetic diversity, evolutionary patterns can be inferred, and variants contributing to the cause of common diseases can be identified.

### 13.4.1 Ethnic Diversity of Rare Disease Alleles

The existence of different disease alleles among ethnic groups is significant both for understanding the origins of the disease in a population and for estimating recurrence risks that will depend on ethnicity. Several examples show the benefit of applying population history to medical genetics.

The thalassemias have relatively high frequencies in many different populations, presumably due to selective advantage (increased relative fitness) of the heterozygotes over the homozygotes against malaria. Mutations in the genes encoding both the  $\alpha$ -chain (chromosome 16) and the  $\beta$ -chain (chromosome 11) of hemoglobin cause thalassemia. Most of the  $\beta$ -thalassemia mutations are single bp substitutions as opposed to the  $\alpha$ -thalassemias, in which complete genes are deleted. More than 80  $\beta$ -chain point mutations that cause  $\beta$ -thalassemia have been described. These mutations have a wide ethnic distribution, with several different common alleles found in Mediterranean, African, and Southeast Asian populations.

Tay–Sachs disease provides another excellent example of ethnic-specific mutations. The most common mutation in the hexosaminidase-A  $\alpha$ -subunit gene (chromosome 15) causing Tay–Sachs disease in the Ashkenazi Jewish population is a 4-bp insertion in exon 11. It is found in 80% of mutant alleles in this population, but in less than 20% in other populations. Three alleles account for 99% of mutations in the Ashkenazi Jewish population. The frequency of Tay–Sachs alleles is also relatively high in the French Canadian population, in which two different mutant alleles have been described. Members of several Acadian families in southwestern Louisiana were found with Tay–Sachs disease; in 11 of 12 disease alleles, the mutation was the 4-bp insertion that is the most frequent mutant allele in the Ashkenazi Jewish population.

Other diseases, such as gyrate atrophy and familial hypercholesterolemia, show similar ethnic diversity in the distribution of mutant alleles. Founder effect (random genetic drift), selection, and gene flow determine the frequencies of mutations in different populations.

### 13.4.2 Evolutionary Patterns

Various types of DNA marker alleles have been analyzed in studies of population structure and evolution, and before the introduction of DNA markers, similar studies were done using blood group and protein polymorphisms. The evolutionary tree derived from these studies suggested four major groupings, consisting of Africa, Europe/Asia, Americas, and Australia/New Guinea, with the most likely origin being the

African branch. Detailed analyses of mitochondrial DNA (mtDNA) and Y-chromosome haplogroups have extended these findings and confirmed that contemporary populations are largely the descendants of people who migrated out of Africa about 50,000 years ago. For example, the mtDNA and Y haplogroups found in southeastern Asia and Australia are distinct from those in the rest of Asia and Europe. This variation is most likely the result of random genetic drift and northern and southern migrations at different times. The Americas were the last continents to be colonized, and as would be anticipated, most native American Y chromosomes belong to a single haplogroup. Interestingly, the results of voyages by Europeans to the Americas and Oceania in the past 500 years are clearly revealed through mtDNA and Y-chromosome analyses. In these populations, European Y-chromosome haplogroups are relatively common, while the mtDNA haplogroups are those of the indigenous population.

Because of sex-specific gene flow and the small amount of the genome represented, studies of historical migration based only on mtDNA and Y chromosome are biased (1). With the availability of next-generation sequencing, entire human genomes can be compared. In fact, a draft sequence of the Neandertal genome has now been completed (2), revealing gene flow from Neandertals to modern humans after moving out of Africa. There is also an extensive amount of genetic variation among African populations (3), with most African-Americans having a mixed ancestry that is not specific to any one African group (4). This high level of admixture can be quite helpful for identifying genetic variants associated with disease or response to drugs.

### 13.4.3 Genome Variation

The advances of the human genome project have renewed appreciation and interest in the study of naturally occurring variation in the human genome. About 90% of human DNA variation is due to single nucleotide base changes. On average, a single bp difference between two human genomes is observed for every 1000 bp. But the odds of finding a difference may be as much as 100-fold greater in some regions of the genome than in others. Single nucleotide polymorphisms (SNPs) are defined as loci with alleles that differ at a single base, with the rarer allele having a frequency of at least 1% in a random set of individuals in a population. In general, the likelihood of finding an SNP is much higher in noncoding regions than in coding regions. (An SNP in a coding region is sometimes called a cSNP.) Most SNPs found in the human genome are thought to have originated long after speciation, but before the separation into different human populations. This explains the observation that human SNPs are usually not shared with primates, but are common to all populations; only about 15% are thought to be “private.” Also, only a

few of the SNP alleles that were present when humans moved out of Africa have become fixed (either 0% or 100%) at this point in time.

As a result of major international initiatives, approximately 10 million SNPs, both common and rare, have been identified in the human genome, and more than 1.5 million have been genotyped in over a thousand individuals from 11 global populations (5). In addition, the detection and characterization of copy number variants (CNVs), which tend to map to duplicated segments, has provided access to important variation, particularly in highly duplicated gene families, which is likely to contribute to some common diseases (6). And recently, the 1000 Genomes Project has generated and cataloged several million more SNPs and CNVs, bringing the total to nearly 20 million. The goal of this project is to discover, genotype, and provide accurate haplotype information on DNA polymorphisms in multiple human populations (7). These extensive datasets provide the population geneticist with a huge set of densely mapped polymorphisms for reconciling genome variation with population histories of bottlenecks, admixture, and migration, and for revealing evidence of natural selection. They also enable informative studies such as pinpointing functional elements affecting gene expression in noncoding DNA, which tend to be in regions of reduced variation (8). Moreover, the knowledge gained from these studies is applicable to many disciplines including forensics, pharmacogenomics, and complex disease research.

### 13.4.4 Identification of Causal Variants for Common Diseases

Earlier in this chapter, the concept of LD was described, and it was mentioned that studies exploiting this phenomenon have been helpful in defining the precise location of disease genes. The complexity of patterns of LD and the extent and explanation of variability among populations are critical factors that are only now becoming understood (9).

A large number of genome-wide association studies have been performed using the millions of SNPs that are now available. These studies have identified genomic regions containing genetic risk factors for many complex diseases, for example, Parkinson disease (10). However, for the majority of such diseases that have been studied so far, much of the genetic influence on them remains to be explained (11).

The availability of massive databases of genetic variation and automated technology for genotyping, sequencing and bioinformatic analysis is significantly enhancing collaborative efforts between population geneticists and molecular geneticists and advancing understanding of many diseases. As we would anticipate, thousands of interesting new questions are arising and the tools to answer many of them are now at our fingertips.

## Biographies

**Bronya J B Keats** is currently a professor in the Research School of Biology at the Australian National University (ANU). From 1999 to 2008, she was professor and chair of the Department of Genetics at Louisiana State University Health Sciences Center (LSUHSC) in New Orleans. Dr Keats received her PhD in human population genetics from ANU in 1976, and spent several years at the University of Hawaii before moving to LSUHSC. Much of her research has focused on linkage and LD mapping, as well as the identification and characterization of genes for hearing loss and neurodegenerative disorders in the Acadian population of south Louisiana. A particular research interest has been genome variation and instability in microsatellites, especially repeat expansions associated with neurodegenerative disorders. She has worked on Usher syndrome and Friedreich ataxia, and is presently involved in promising preclinical studies using cellular and mouse models for these diseases.

**Stephanie L Sherman** obtained her PhD in Human Genetics from Indiana University School of Medicine in 1981 and is currently a professor in the Department of Human Genetics at Emory University in Atlanta, GA. Her training is in the area of genetic epidemiology and she has been involved in coordination of multisite projects to ascertain families for gene mapping studies of complex traits and genotyping/phenotype correlation studies. Currently, she is involved in research to understand the genetic and environmental risk factors associated with human chromosome nondisjunction, particularly trisomy 21. In addition, she and her colleagues have worked on strategies to identify susceptibility genes related to specific birth defects associated with Down syndrome. She also focuses her research on identifying genetic factors that increase the risk for fragile X premutation-associated disorders including primary ovarian failure (FXPOI) and tremor/ataxia syndrome (FXTAS).

## Pathogenetics of Disease

Reed E Pyeritz

Perelman School of Medicine at the University of Pennsylvania,  
Philadelphia, PA, USA

*To wrest from nature the secrets which have perplexed philosophers in all ages, to track to their sources the causes of disease, to correlate the vast stores of knowledge, that they may be quickly available for the prevention and cure of disease—these are our ambitions.*

Sir William Osler, 1902 (1)

*The great ease with which molecular information can be collected on the genomes of higher organisms will tempt many. We can inevitably expect vast compendia of sequences but, without functional reference, these compendia will be uninterpretable, like an undeciphered ancient language. Many people and many computers will play games with these sequences, but we will have to find out by experiment what the sequences do and how the products they make participate in the physiology and development of the organism. Thus, although the analysis of the genotype has been taken care of, we still need better ways of analyzing phenotypes. Many of us are ultimately interested in the causal analysis of development and the reduction of the complex phenotypes of higher organisms to the level of gene products. This is still the major problem of biology. We must understand what cells can do because all of what we are is generated by cells growing, moving and differentiating.*

Sydney Brenner, 1973 (2)

*The effort spent on the identification of genes is likely to prove only a small fraction of that required to work out their normal function in the tissues in which they are expressed. Yet that is where clues to the treatment and prophylaxis of disease are most likely to arise.*

John Maddox, 1994 (3)

### 14.1 INTRODUCTION

The foregoing quotations emphasize that the general theme of this chapter—all that occurs between the gene and the bedside—is not a new one. The true promise of the Human Genome Project only began to be realized when our genome was sequenced, and the really hard work remains (4,5).

At the outset, the definitions of four terms are fundamental to everything that follows. All deal with the causation of phenotypes, and they are distinguished as to method and scope of enquiry.

Etiology is the study of the causes of a phenomenon and, in the medical context, of disease. Its method is to discover the association between factors that are thought to be causes and certain features that we wish to explain.

The goal and method of the discipline are strictly empirical (“black box”), with at best minor interest in discerning the actual mechanisms involved. For instance, there is a heavily documented etiologic relationship between the total cholesterol level in plasma and the incidence of atherosclerosis. However, whether the former directly causes the latter or the relationship is more oblique is as yet unresolved.

Pathogenesis is the study of the mechanisms by which the etiologic factors are converted into disease states. For instance, the etiologic role of cholesterol in atherosclerosis has been ascribed to the infiltration of oxidized low-density lipoprotein into the arterial wall (the insudation theory); to the stimulation of organization and repair of small arterial thrombi (the encrustation theory); to the promotion of cellular and humoral immune processes

within the arterial wall; and to the secondary accumulation of cholesterol in areas of minor initial damage. Study of these rival, or perhaps complementary, explanations falls within the domain of pathogenesis.

Genetic etiology is a more specialized topic that deals with the properties of the genetic causal factors of disease and how they behave. Mendel's laws, which were formulated before anything was known of the genes and their mechanisms, are arguably the high point of genetic etiology. A positive family history for early coronary artery disease is widely recognized as an important risk factor in the cause of myocardial infarction, with no appeal to explicit mechanisms, even genetic (see Chapter 20). Yet there are undoubted genetic versions, such as the Werner syndrome (OMIM\*277700), an autosomal recessive disorder with premature aging and accelerated atherosclerosis (see Chapter 18).

Pathogenetics, a condensation of "genetic pathogenesis," is the study of how anomalies in the genome are converted into phenotypic disorders. Atherosclerosis has many genetic and nongenetic causes (see Chapter 55). Its pathogenesis has occupied decades of intensive study costing billions of dollars, and it can be fairly stated that the pathogenesis is still uncertain (6–10). One explicit instance of progress in an etiologic component is familial hypercholesterolemia, an autosomal dominant disorder (OMIM\*143890) associated with precocious atherosclerosis. A pathologic mutation in the *LDLR* gene causes one of at least five types of defects in the cellular receptor for low-density lipoprotein (Table 14-1); the result of any such mutation is disruption of cholesterol homeostasis and overt disease of early onset in nearly all instances. This understanding was the first major insight into the pathogenetics of this complex phenotype, and was recognized with the Nobel Prize in Physiology or Medicine to Brown and Goldstein in 1985.

In this chapter, the emphasis is on disease, while stressing the relationship of genetic processes to ordinary developmental mechanisms and maintenance of the healthy body, known as orthogenetics. One such concern is preserving an intact vascular system. Minor leaks

in the vascular tree are mended by the hemostatic plug, comprising platelets and fibrin. At times, this mechanism may become exuberant, resulting in thrombosis, which may occlude a strategic blood vessel. In turn, the thrombus may be covered by endothelium, with its remains, sealed in the arterial wall, perhaps converted into an atheromatous lesion. This gradation points out the perils of drawing sharp boundaries between the so-called normal and abnormal states, boundaries that are neither necessary nor illuminating. Precise definition of a disorder, although an important question in its own right, is a luxury that we cannot afford here (10; see Chapter 2). For this reason, orthogenetics and pathogenetics are best seen as parts of a single continuous field of enquiry (11). Understanding the phenotype comes from the interactions among the insights from many disciplines.

## 14.2 THE SCOPE OF ABNORMAL PHENOTYPES: DISEASE AND MALFORMATION

Conventionally, we distinguish malformations from diseases. Both terms are indefinite, but that need not concern us unduly. However, other challenges cannot be escaped so easily. It is a truism among pathologists that disease occurs only in the living. On the one hand, a cadaver cannot undergo poisoning, suppuration, or neoplasia. On the other hand, instantaneous death by catastrophe of a healthy person may occur without any disease even being started. Disease comprises both a disruption and a reaction to it: homeostasis; inflammation and its sequelae (resolution, repair, and regrowth); curtailment of activities, whether voluntary or by invalidism; and diverse concealing devices ranging from epistasis to psychoneurosis.

There are various ways of exploring these devices, but they call for some circumspection about topics that we shall now address.

## 14.3 PHYSIOLOGIC HOMEOSTASIS

Homeostasis, a mainstay of physiology, is a concept attributed to Bernard (12), studied and named by Cannon (13), and cast in formal terms by Wiener (14). It involves cybernetic devices that maintain the inner environment of the organism in a state that favors normal functioning. Despite its cardinal role in both normal and disturbed physiology, homeostasis has been astonishingly neglected in medical genetics. Its characteristic pattern is to offset departures of a measurable characteristic, such as body temperature, glucose concentration, or blood pressure, from a steady state that is in some sense optimal (the homing value). The size and direction of the response vary with the perturbation, features that put it beyond the scope of the methods most quantitative geneticists use, which are founded on Galton–Fisher theory (15).

**TABLE 14-1** Effects of Mutations in *LDLR* on the Gene Product

Mutation Class	Consequence
Null	No receptor protein
Transport defective	No or reduced receptor at cell surface
Binding defective	Normal receptor number; absent or reduced binding of LDL particles
Internalization defective	Normal receptor number and LDL binding; absent or decreased endocytosis of LDL
Recycling defective	Normal receptor number, LDL binding, and endocytosis; no or reduced release of LDL and recycling of receptor to cell surface

LDL, low-density lipoprotein.

Two main structures characterize the response of a homeostatic system to a perturbation (16). One structure is the precise disturbance to which it is responding. Some models suppose that the response is to the current information only. Others suppose the system to be responding as well to data recorded indefinitely far into the past. The second structure is the form of the response. It will always be of opposite sign to the displacement. If its size is some multiple,  $b$ , times the displacement raised to some power,  $k$ , it is of order  $k$ . If  $k=1$ , the process is linear; if  $k=0$ , it is of zero order. Intermediate values of  $k$  are processes of fractional order, and higher values are quadratic, cubic, quartic, or of noninteger or mixed orders, and so forth. The zero-order process is the simplest and resembles a simple domestic thermostat.

What lends special interest to biologic processes lies in that innocuous phrase “current information.” Messages travel at finite velocities. In cosmic terms, transmission through nerves is slow, and considerably slower through hormones. So the information is at best always somewhat out of date: a lag time ( $L$ ) may or may not be fixed and homogeneous. For instance, the sensors monitoring blood gases lie some way downstream from the apparatus that modifies them, the lungs. The latest information will be out of date by at least 10s (the transit time). Sometimes delay is gross: The response of red cell production to high altitude takes weeks. Lag introduces new and important features not present where the response is instantaneous. For example, in a linear system, if the product  $bL$  exceeds  $\pi/2$ , a wild (ever-amplifying) oscillation results that, left unchecked, would destroy the whole organism. If  $bL$  is negative, feedback is positive, which would also be fatal in most physiologic systems. Thus, both extremes are harmful. Darwinian selection will constrain the actual value well between these limits, but that state is not proof against pathologic lengthening of  $L$  during life, such as happens in some forms of type 2 diabetes mellitus.

Systems of fractional order are metastable: Minute departures from the homing value set up perpetual oscillation, the amplitude of which depends on  $b$ ,  $L$ , and  $k$ , but in no way on the initial displacement. While oscillation vitiates the primary stabilizing goal of homeostasis, it is a simple, reliable generator for rhythmic processes. It may explain how success in various physiologic maneuvers (e.g. breathing of the newborn, menarche and menopause, electric shock in ventricular fibrillation) stands or falls by and whether the first step can be provoked. Much the same argument would explain bipolar mood disorder and particularly those puzzling, so-called endogenous depressions in which the initiating factor may be so trivial as to be totally overlooked (17).

Processes with  $k>1$  have a property that is very rare, perhaps unique, in biologic models. If not large enough to cause wild oscillation, a perturbation causes

a finite number of oscillations only, such as occurs in unsustained clonus (18).

Much of the detailed workings of homeostatic systems depend on enzymes, receptors, and ligands, all of which exhibit genetic variation. Perturbations are a fact of life, and physiologic homeostasis to correct them is ubiquitous. No reasonable system can correct them fully and instantaneously. Furthermore, as we have seen in the control of periodic functions, other competing benefits of homeostasis are to be considered. We attempt to give a brief summary of the advantages and disadvantages of the various types of functions in Table 14-2. Wherever there is an inescapable lag, there will be added difficulties in achieving a prompt response without undesirable overshoot and perhaps even total loss of control. Optimal states may be very complicated, which we consider difficult to develop by wholly random evolution. This fruitful field in the genetic exploration of disease has been largely neglected.

For many bodily characteristics, health is the avoidance of extremes. Diseases may then result from excess or deficiency, and the dynamic reactive component will aim to restore the optimal. Now, in Galton–Fisher theory, any variable genetic component becomes fixed in magnitude at conception. By contrast, the responses of health and disease are perpetually exercised in a fashion variable in both degree and direction, in accordance with the size and sign of each perturbation. It is scarcely surprising that Galton–Fisher theory, so useful in static traits, is irrelevant to most diseases. From time to time, Galton–Fisher theory has furnished more refined descriptors such as Pearson’s threshold model in congenital heart disease. But it is difficult to cite any instance in which these maneuverings have led to yet deeper questions and understanding of disease, its cause, its pathogenesis, or its genotypic fate at large (genetic population dynamics). History demands that clinical geneticists not discard Galton–Fisher theory

**TABLE 14-2** Some Broad Patterns of Response in Physiologic Homeostasis

Generating Specifications			
Pattern of System	$L$	$b$	$k$
Monotonic amplification	Any	$<0$	Any (positive feedback)
Pure drift	Any	0	Any
Monotonic decay	0	0	Any
Fast decay for big perturbations	Small	Large	Large
Fast decay for small perturbations	Small	Large	Fractional
Perpetual steady oscillation	$>0$	Any	$<1$
Damped oscillation <sup>a</sup>	$\pi/2b$	$>0$	1
Temporary oscillation	$1 \pi/eb$ to	Moderate	$1 \pi/eb$
Wild oscillation	Moderate	Otherwise	$>1$ , then decay

<sup>a</sup> $L$  may assume values only in the open interval shown.

altogether. However, we believe this theory to be too restricted to be of much interest in pathogenetics or orthogenetics, and it often obfuscates enquiry.

### 14.3.1 Limited Scope of the Galton–Fisher Theory

The original conflict between the Pearsonians (in the Galtonian tradition) and the Batesonians (in the Mendelian tradition) was at first thought to be irreconcilable. Fisher's reformulation recasts them in more unified terms. Two serious gaps were left that we have been slowly and painfully discarding since the time of the epochal papers on the specific chemistry of the gene. Fisher's argument was centered on the mean and variance of binomial and multinomial variables, which are strictly not genes but statistical properties of genes. It solved the problem, but the questions resulting were much more intransigent. Linkage analysis and its analytic difficulties notwithstanding, it is an analogous mathematical descriptor. The elaborate formal theories for it have never had a rationale with a literal meaning. Linkage is now so refined and reconciled with detailed gene assignment that the false character of linkage anatomy scarcely matters any more. But we can make allowance for the fact that, even in combining small linkage intervals, Fisher's binomial assumption may yet prove misleading (because of non-additivity, etc. in particular cases) and require special handling.

## 14.4 MULTIVARIATE NORMAL DISTRIBUTIONS AND THE THRESHOLD MODEL

Galton's reconciliation with Mendel was based on multivariate normal theory, and we know of many instances—arguably the great number of instances—in which the assumptions are in fact sound. Fisher recognized this fact very well and specified it in assumptions. But many papers in clinical medicine on “the inheritance” of quantitative aspects of disease have fallen into methodological disrepute without having ever been repudiated formally. We suggest that (like linkage analysis) Pearsonian quantitation of disease be treated as a descriptor of statistical properties of genetic disease and no longer as either an explanation or an account of it. It is only fair to Pearson's explicit warning (which has been widely ignored) that “quantitative genetics” should not be applied to putative “threshold traits” when no threshold has been identified, has been the object of sound surmise, or both. Even so, the assumption of approximate Gaussian normality calls for some serious justification. As understanding of disorders gradually improves, the need for approximations becomes harder and harder to justify. We suggest that the now outmoded practice should be abandoned.

### Example

Many details suggest that most cases of type 2 diabetes mellitus at their outset are due to neither defective nor deficient insulin, but to impaired insulin regulation. Arguably, hyperglycemia and hypoglycemia are the same condition in different phases, as illustrated by potentially rapid oscillations between the two states in “brittle” diabetes. The interpretation of two apparently opposite disorders as a manifestation of instability of a single trait is not so startling as it may first appear. Besides the obvious precedent of bipolar mood disorder, there are many analogs, such as postural hypotension, dysautonomia, and anorexia–bulimia (19), but all such conditions would be inaccessible to Galton–Fisher theory, centered as it is on the first two moments of the Gaussian distribution as a gauge of the variation of means. Galton–Fisher theory is not sensitive to variation in tolerances as a segregating trait. Purely technical use of Galton–Fisher theory in almost purely genetic bipolar disease may yield heritability at or close to zero and lead to the mistaken conclusion that the disease is nongenetic. Diabetes occurring early in life is usually type 1 and insulin dependent, and its etiology has long been recognized to have both environmental and multiple genetic components (see Chapter 86). One of these genes is the insulin locus, at which variation in tandemly repeated sequences 5' to the coding sequence affects regulation of insulin transcription (20,21).

## 14.5 ONTOGENESIS OF ANATOMIC STRUCTURES: ANGULAR HOMEOSTASIS

A colleague from the humanities identifies a fundamental problem: “A novel is half a million words long and one line thick. How can a novel be coherently written?” This evocative image is the very nub of the pathogenetic challenge for large and complex structures. How is a linear (single-dimensional) code “one nucleotide thick” in the genome to be translated into the fetus? The objective involves three dimensions in space and one in time. That the whole must be carefully orchestrated is self-evident. (The linear genetic code certainly has spatial orientation; however, this levorotatory optical asymmetry cannot convey any genetic information, since the essence of a code is the possibility of an alternative, and no dextrorotatory alternative is known.)

Perfect assembly of a spatial structure is rarely enough: it must commonly be adequately matured by a specified ontogenic timeline. Development of the lips and palate calls for exquisite timing. Even in genetic etiology, the ontogenic phenomenon of “time windows” indicates some state of minimal precision. This complex feat of organizing form and timing may perhaps be achieved by “dead reckoning,” by rigorous specifications and a relentless timetable. However, there is evidence that the system is more robust than that, because of what Waddington (22) called homeorrhexis. This process in ontogeny, which we call angular homeostasis, is akin to Bernard–Cannon homeostasis (23,24). In it, discrepancies between the current and the ideal states of ontogeny are discerned and corrected. There is plenty of biologic evidence from age-old observations of tropisms and taxisms and from

modern studies of target tracking and predation to make the whole strategy highly plausible. What exactly the cybernetic details are and how they operate are emerging in expressly and explicitly quantitative chemical terms (25,26). But the greater efficiency that continuous sensing and correction enjoys over unbending protocol is evident to anyone who has experience both of the minutely directed process of firing a gun at a moving target, where the path of the bullet, once fired, is beyond correction.

If usual development is difficult to reconcile with a linear code of instruction, so too is maldevelopment. In this “postgenome” era, a variety of approaches will be required to address both the normal and the abnormal (4,5).

### Example

Phenotypes associated with additions or deletions of many genes, such as in aneuploidy, or deletions or duplications of contiguous genes (“genomic disorders”) have stimulated considerable debate about pathogenesis (see Chapters 43 and 45). On the one hand are those who hold to the reductionist position that the phenotype reflects, in essence, mass action of too much or too little of the products of the affected genes. One result is the attempt to identify, for example, the gene or genes on chromosome 21 responsible for the cardiovascular malformations in the Down syndrome. On the other hand are those who see the phenotypes as the result of complex interplays among multiple genes, which are being expressed in a local environment that is asynchronous with normal development.

### Example

Coding the laterality of the brain is a more perplexing problem than ever. For the choice now does not seem to be an anatomic one at all, but a question of which information and which kinds of mental process shall be assigned to the left side and to the right. Wholly indifferent, random assignment is theoretically possible (27). However, although the facts have been distorted in the past by social prejudice, there still seems to be a higher rate of “left brain dominance,” and although the patterns are not altogether clear, there is evidence that genetic factors are at work. The genetics of handedness, as a surrogate for cerebral dominance, has been studied for decades. According to one hypothesis, mothers tend to support infants using their left arm, perhaps so to soothe them with the sound of the maternal heart. Thus, mothers who were by nature right-handed (dextral) would find some evolutionary favor (28). Another hypothesis suggests that left-handed warriors were more successful (29). What is clear, however, is that left-handedness is less common in all human populations, despite some geographic variation. Thus, whatever selective pressures favor left-handedness must be balanced by some negative ones for the trait to remain less common. The prevalence of left-handedness decreases with age (29). Whether sinistrality itself reduces life span, or serves as a marker for underlying neuropathology (perhaps related to cerebral dominance), remains unclear.

As to the vastly more complex problem of how the brain is constructed out of linearly arranged genetic instructions, the only mechanical model that comes to mind—and it is a feeble one—is the process of simultaneously loading and configuring a language onto a

computer. Present general theory of the construction and operation of the brain taxes the imagination to the limit. But one, especially a geneticist, cannot help but be impressed by the reliability of the system.

### 14.5.1 Elaborateness of Repair

One is struck by the reciprocal relationship between ontogenic robustness and recuperative power. The brain is the most highly organized structure but, while having some functional capacity to recuperate from damage by the fluidity in allocating space to functions, only recently has it been shown to have any regenerative power of parenchymal cells at all. The structure of the kidney may be less critical than that of the heart but, like the heart, it has little capacity to repair damage to its architecture. Anatomically at least, the liver is both less critically structured and more robust, but has much greater forces of recuperation. Tissues such as skin, bone marrow, spermatogonia, and intestinal endothelium are still less elaborate and are therefore ready for regeneration as to be notorious sites of sensitivity to mutagens.

### 14.5.2 Life History

A natural feature of the impact of a disorder is how it affects well-being, fertility, and length of life. These three, although distinct, are obviously connected; yet the traditional methods of analysis pay little attention to this fact. Discussions on fitness make much of the fact that clinical, genetic, evolutionary, athletic, and moral fitness are so different that they must be discussed separately. Indeed, excellence in one may go with mediocrity, even total incompetence in another. The superathlete may be sterile and morally bankrupt. The puny may live a long life free of disability. The fertile may be negligent in the care of their progeny. But it is absurd to suppose the several types of fitness to be totally unconnected. The issues are too large to deal with here, and we consider only the relationship between clinical fitness and length of life.

It is useful to distinguish between the unfolding of a disease and the impact of its complications. The wholly static disorders are mostly trivial: red–green color blindness, tone deafness, pentosuria, synophrys, and the like. The usual pattern of deterioration may vary greatly. In severe cardiac malformations, the disability is evident at birth or soon after. Even so, major complications such as pulmonary hypertension and reversals of flow through a patent ductus arteriosus or an atrial septal defect may occur late. In hereditary polyposis coli, it is the course of the disease itself—the long latent phase, progressive polyposis, and malignancy—that is the chief concern, while other complications (except those due to therapy) are minor. By contrast, Alzheimer disease (OMIM\*104300) often appears so late that it is frequently obscured by intercurrent and competing diseases. Indeed, until recently “senile dementia” was viewed by some as a

concomitant of aging, and not as a disease. But while the duration of Alzheimer disease averages perhaps 5 years depending on diagnostic finesse and management, it is surprisingly difficult to find evidence that the patients ever have neurologic deaths. They seem to die of the complications (e.g. trauma, intercurrent infections, malnutrition) that occur at much increased risk.

The notion that well-being is eroded by overt catastrophes (e.g. strokes) or those imperceptible insults (e.g. chronic pyelonephritis) that we identify as “wear and tear” is so appealing that we are led, almost unconsciously, to accept multistage models (belonging to the broad Erlangian class). Where the genetic disorder becomes manifest early (as in Duchenne muscular dystrophy), the competing risks are small, and the pattern of deterioration is dominated by a single class of insults, with the typical survivorship curve positively skewed (i.e. with a long tail to the right). When the onset of disease is late, the patient shows the characteristic multiplex pathology so familiar to the geriatrician: damage in several body systems, so that it is often difficult to say which is the final cause of death. The survivorship is then often negatively skewed. That class of survivorship in which death is due to whichever of several partially damaged systems fails first is a “bingo” model, usually given some qualifying term denoting the structure of the decay in the individual systems (e.g. “bingo-gamma,” “bingo-logistic”). It is a common state that flagrantly violates the assumptions underlying Galton–Fisher theory.

### 14.5.3 Nature and Nurture Reconsidered

Part of the notorious “nature–nurture” vision of medicine (i.e. the image that disease is in origin either genetic or environmental or between them) was that it was suggested (we presume as a pun) for making sure that in the consequences nothing is overlooked. We have serious doubts that even at its best it was ever an illuminating axis. One merely has to think of whether scurvy is a vitamin deficiency or (so far as we know) an inborn error of metabolism. In a fair-skinned population at the equator, sunburn is almost purely environmental. In a mixed population of pure fair-skinned and pure black-skinned individuals, it will be almost purely genetic. That radical and basically meaningless anomaly is well known. There is also the hidden and unsatisfactory notion of anomalous division into classes that are exclusive and exhaustive. This dichotomy is not only logically incoherent but also practically unsound. The difficulties lie in the uneven logic. An environmental disease requires at the very least a black box empirical proof. Empirically, a Mendelian trait either must powerfully follow from birth the pattern of Mendelian inheritance or must be shown to be due to an inherited polypeptide anomaly or various combinations of them. Again, a chromosomal trait must at some scale be cytologically evident from birth. Where a “multifactorial” trait is concerned, however, scarcely

any proof at all is called, and only the feeblest criteria. Inevitably, then, anything that is discarded from lists of empirical causes, Mendelian traits, and chromosomal anomalies will too often, sometimes alarmingly often, be treated as some nonspecific assembly of disorders likely (especially if occurring in early life) due to “genes,” a claim that is almost disprovable (31). Consider a few telling consequences:

- Homosexuality has been declared a Mendelian trait, although its frequency is continually being identified as high, even preposterously high because it must severely impede reproduction and play havoc with the most fundamental principles of linkage.
- It has long been called into question whether hysteria exists at all (32). Yet, though its very existence is still equivocal, “hysteria” remains very common.

## 14.6 PATHOGENETICS OF REFINED TRAITS

The most important process known in genetics is generating the primary sequence of the polypeptide in the proper cell at the right time. This is attained by the elaborate apparatus of genetic coding, transcription and its regulation, and translation, which is highly conserved in evolutionary time, but the high organization largely ends at that stage. Once formed, the polypeptide assumes its secondary and higher structure by processes that are little understood; aside from posttranslational modifications catalyzed by enzymes, there seems to be little need to direct these processes. The polypeptide quickly assumes a stable low-energy state. Whether it ever becomes completely fixed is not readily established. But in or near that state, it functions most efficiently. The subsequent fate of the polypeptide may be largely random.

### Example

The theory of red cell survival suggests that the cell is eventually destroyed by random wear and tear, and the hemoglobin with it. However, survival of the whole is still shortened by some mutant forms of the primary structure of hemoglobin or of components of the erythrocyte wall.

The speed at which the polypeptide is made is certainly important. For instance, sickle hemoglobin is manufactured more slowly than the wild-type, such as to lead to a representation in the heterozygote in a ratio of 2:1 to 3:1. Furthermore, in heterozygotes, A and S hemoglobins tend to be concentrated in particular cells. However, one does not ordinarily regard translation (as opposed to transcription) primarily as a timed or quantitative process. Posttranslational modification is also sensitive to time. A mutation that results in substitution of a glycine in the triple-helical domain of type I procollagen results in slower winding

of the helix. This in turn exposes for a longer time critical amino acids to the enzymes that catalyze modifications, such as glycosylation. The net result is a much more “damaged” molecule than a simple amino acid substitution might predict. But there is even a higher order effect possible when a protein is malformed or otherwise damaged as it traverses the cellular machinery. The process of translocating proteins across membranes is being elucidated (33). A key component is the endoplasmic reticulum (ER). When the ER encounters a malformed protein, processing slows; if severe, a situation of “ER stress” ensues, which can lead to marked cellular dysfunction, even cell death (34–36). Interestingly, the cellular phenotype may be the same for different mutations that affect entirely separate proteins. Understanding the importance of ER stress to the overall phenotype may afford a generic approach to therapy, whereby refolding of the mutant protein is facilitated (37).

Where the components are interchangeable (e.g.  $\beta^A$ - and  $\beta^S$ -globins), systems are appropriately described by their corporate properties. Where the numbers are large (e.g. numbers of erythrocytes), the usual device is the probabilistic model; and where the numbers are even larger (e.g. molecules), deterministic methods greatly simplify the analysis with negligible loss of accuracy. However, whatever the value of deterministic models in microbial populations, they have little place in studies of human beings; even in molecular studies, they must be handled with circumspection. This is a major difference between classic population genetics and the highly individualized character of medical genetics.

## 14.7 PATHWAYS AND MULTIPLE-STAGE PROCESSES

Two highly refined approaches have much in common and may, in certain circumstances, be united by a single theory. There is much to be gained by dealing with them interchangeably in stochastic and chemical terms, by seeing the usual dynamics as probabilistic. However, we shall first treat them separately.

### 14.7.1 Simple Pathways

The simplest possible process involves synthesis of B from A by enzyme ab (Figure 14-1). There are three potential deleterious consequences:

- Precursor toxicity: Because ab fails, A accumulates and proves harmful. Alkaptonuria (OMIM\*203500) is such a disorder, as are most enzymopathies in catabolic pathways, such as lysosomal storage disorders.
- Product deficit: Because ab fails, B is reduced or absent. Examples include the various forms of albinism due to failure to produce pigment (e.g.

**FIGURE 14-1** An enzyme, ab, catalyzes conversion of substrate A to product B.

**FIGURE 14-2** An enzyme, ab, catalyzes conversion of substrate A to intermediate B, which is converted to final product C by enzyme bc. A defect in ab impairs production of C. The gene specifying ab is epistatic to that encoding bc.

OMIM\*203100) and most enzymopathies involving posttranslational processing of proteins. In a few mammalian species, the inability due to deficiency of one enzyme to synthesize ascorbic acid is another example. This example raises the fundamental issue of whether deficiency of this enzyme in all humans excludes it from the category of “disease.”

- Combined product deficit and precursor excess: The glycogen storage disorders are examples (e.g. OMIM\*232200). The glycogen that accumulates disrupts cellular and tissue processes, while failure to release glucose from glycogen leads to hypoglycemia. Phenylketonuria (OMIM\*261600) is another such example; phenylalanine is toxic in excess, and synthesis of tyrosine is impaired, resulting in the pleiotropic manifestations of phenylalanine hydroxylase deficiency.

This elemental pattern extends to the three-step process:  $A \rightarrow B \rightarrow C$  (Figure 14-2). If A is absent, then B is lacking, and C cannot be synthesized. This suppression is epistasis; the gene governing the first step is epistatic to that governing the second. The classic example in humans is the rather trivial Bombay blood group phenomenon (OMIM\*211100) in which the failure to generate H substance destroys all means of expressing the ABO blood group phenotype.

### Example

Consider a typical multistage metabolic pathway, such as the synthesis of cholesterol or thyroid hormone. Each step is under the control of an enzyme. It will be at once evident that total failure at one or more steps means total blockade of later stages and that substrate accumulates before the first failed step. The gene for the enzyme at any step is therefore epistatic to all subsequent steps. The combined effect of defects in all genes will be the same as that of any (non-empty) subset of defective genes. In this it is quite different from the usual additivity of traits in Galton–Fisher theory.

### 14.7.2 Branching Pathways

We distinguish two kinds of branching pathways: the open and the closed. In the open type (Figure 14-3A), the branches do not rejoin and pool their products; thus, they compete for substrate, and the flow through each is correspondingly

**FIGURE 14-3** Metabolic pathways with branches. (A) Open branched pathway. (B) Closed branched pathway.

decremented. In the closed type (Figure 14-3B), the paths rejoin, and the result is a parastasis; two or more pathways run in parallel, which accelerates the entire process and acts as a fail-safe device should any of them fail. This scheme can be used as an advantage in treatment, such as by promoting remethylation of homocysteine to methionine through an alternative pathway dependent on the cofactor betaine (see Chapter 92). Those classic inborn errors of metabolism that lack adequate alternate pathways are the most severe clinically. Their rarity argues that metabolic processes without auxiliary paths are the exception, and the selective disadvantages may explain why.

On the other hand, a defect in one branch of a pathway may generate all or most of its pathology by leading to overflow through the alternative branch. For example, a defect in the enzyme hypoxanthine-guanine phosphoribosyltransferase (OMIM\*308000) leads to overproduction of phosphoribosylpyrophosphate. This in turn drives overproduction of purines, which leads to hyperuricemia, hyperuricosuria, and gout (see Chapter 95).

### 14.7.3 Pathways with Feedback

Metabolic pathways may be actively regulated in some cases by demands downstream. Negative feedback, positive feedback, or both can achieve a desired rate of processing or level of synthesis. This represents a form of physiologic homeostasis. Production of most hormones involves feedback at multiple levels. For example, estrogen is secreted by ovarian follicular cells in response to the anterior pituitary hormone and follicle-stimulating hormone (FSH); estrogen in turn feeds back on both the hypothalamus, to inhibit production of gonadotropin-releasing hormone, and on the anterior pituitary, to inhibit release of FSH, thereby modulating estrogen production and preparing the endometrium for implantation. Once an embryo implants in the endometrium, synthesis of chorionic gonadotropin signals the ovary to continue production of progesterone, which maintains the endometrium as a nurturing environment for continuing the pregnancy.

### 14.7.4 Multiple-Hit Processes

A metabolic process involving several steps may, where necessary, be viewed in more quantitative terms. In the

synthesis of insulin in response to a carbohydrate load,  $(n+p)$  steps are involved, but physiologic impact occurs only in the final  $p$  (potent) steps where physiologically active forms reside. The lag time for the response, then, is that for the transit through the system, and the first  $n$  (neutral) components, the inert precursors are neither here nor there. In this sense, what matters is only the process as a whole; permutations of the components do not matter.

#### Example

At a more clinical level, one may cite the proposals that the onset of Alzheimer disease (38) and aortic dissection in Marfan syndrome (39) are multiple-hit processes.

### 14.7.5 Multiple-Compartment Models

To deal with chemical processes in the foregoing fashion has certain uses, notably in understanding steady-state processes. Where changes need to be more rapid, however, we must take a more quantitative approach. Many of the processes of converting one class of compound into another are of so-called zero-order kinetics, that is, other things being equal, the rate of transfer equals the concentration of the substrate multiplied by the Michaelis constant,  $m$ . In a system without replenishment of substrate, these conditions define the negative exponential process, and the mean time for conversion, the waiting time, is precisely  $1/m$ . This pattern may be viewed from two perspectives: first, as a chemist sees it, deterministically conforming to the law of mass action; and second, as a probabilist sees it, a random exponential (one-hit) process in which every eligible molecule is at a fixed instantaneous hazard of change. As long as the number of molecules remains large, the distinction hardly matters. But the probabilistic model is more appealing because of its wider relevance in biology (e.g. when the number of decaying items—molecules, body cells, recurrent bodily insults—is small, and random uncertainty may no longer be safely ignored). Assuming that each step operates independently, the transit time through the metabolic chain is then the sum (or, strictly, convolution) of the waiting times of each step. The whole is termed a multiple-hit process. Its mean value is the sum of the waiting times, that is, the sum of the reciprocals of the Michaelis constants. (Throughout this discussion, the reader may be struck by the precise analogy to the corporate properties of the resistances in an electrical circuit.)

It will be clear that, the smaller any particular Michaelis constant compared to constants for steps elsewhere in the chain, the larger is its reciprocal and the greater its impact on the whole transit time. Moreover, other things being equal, for any given variation in  $m$ , the smaller the mean, the larger the variation in its reciprocal, and the more sensitively the impact of variations in it will be detected. At some, quite arbitrarily small, value of  $m$

and large value for its reciprocal, this dominating step is termed the rate-limiting step; viewed genetically, if this step is itself Mendelian, the whole will be termed Mendelian. It will be evident that the conventional distinction between Mendelian and Galtonian (“multifactorial”) traits is both vague and arbitrary.

## 14.8 MOLECULAR PATHOGENETICS

When the defect in a genetic disorder is described at the level of the mutation, the object is at, or very close to, the genotype, and the field of inquiry is etiology. Anything more remote from the mutation represents phenotype and at least the first layer of complexity in the pathogenetics (Table 14-3). Thus, the resolution or sensitivity of the methods being brought to bear on the investigation of how the disorder arises determines how closely the mutation can be approached. The clinician has long had to deal with crude tools—stethoscope, tape measure, electrocardiogram, radiograph, urinalysis—to define the phenotype; what generally results is a perception of pathogenesis that is shallow, often complex, even confused. At the bedside, and even in the clinical laboratory, one usually sees only the leaves on the pathogenetic tree. Advances in clinical chemistry, biochemical genetics, cytogenetics, immunology, noninvasive and invasive imaging of many types, and pathology have all led to a more radical, hence sensitive, discernment of what is wrong with the patient and elucidation of pathogenesis. All these advances have facilitated in brushing aside the leaves and clambering part way down branches toward the trunk of the pathogenetic tree (Figure 14-4).

This figure also illustrates a fundamental characteristic of many human phenotypes termed pleiotropy. This word encompasses several concepts in biology; here it refers to multiple, even seemingly unrelated, aspects of the same syndrome. Indeed, syndrome embodies this notion of several clinical properties “running together.” Each of the leaves on the pathogenetic tree represents an aspect of the phenotype, connected through the limbs of pathogenesis. The analogy breaks down in that, while all leaves appear similar, the clinical details of the phenotype may be quite diverse. For example, dislocated lens, elongated digits, dural ectasia, and aortic root aneurysm are cardinal manifestations of Marfan syndrome, but outwardly bear no connection to each other (see Chapter 153). These features are all rooted in mutations in the gene encoding a large structural protein (*FBNI*), and at the first level of pathogenesis, share defects in an extracellular structure, the microfibril (corresponding to the trunk in the figure). However, microfibrils vary structurally and functionally in different organs and tissues, so each of the limbs of the tree heads in its own direction. The molecular bases of pleiotropy are as diverse as the features of some syndromes (40). For example, the complexity of some Mendelian inborn errors of metabolism is due to the mutant enzyme having functional roles

**FIGURE 14-4** Pathogenetic tree for a Mendelian condition. Leaves correspond to the phenotypic features, detectable by bedside investigation. Branches represent the pathogenetic pathways leading to organ- and tissue-specific pathology. The trunk corresponds to the gene product. Roots indicate the cause, in this case, the mutation.

beyond that in the specific metabolic pathway at issue. The extent of such “moonlighting enzymes” in human biology is uncertain (41).

The phenotype can be explored systematically, beginning with the first product of the mutant gene, messenger RNA (mRNA) (Table 14-3). Various defects in the structure and amount of a given mRNA can be described, albeit only with considerable effort and sophistication in techniques. The thalassemias (see Chapter 71) constitute one group of diseases that beautifully illustrate the molecular pathology of mRNA.

It is more feasible and instructive to focus on the stable product of most genes, the protein, and describe the types of molecular pathology that arises from mutation. In the most fundamental terms, a mutation can affect

the quantity of a protein, the quality of a protein, and occasionally both aspects. The quantity of a protein synthesized by a gene is regulated at the level of transcription, by promoters, enhancers, and other locus control elements, and at the level of translation (see Chapter 5). Mutations in any of a number of sites, *cis* and *trans*, to the gene of interest can affect the amount of protein produced. Usually, but not always, production from mutant alleles is decreased. One class of mutation that has garnered considerable attention is the expansion of a trinucleotide repeat within or, more commonly, outside the actual coding sequence (see Chapter 7). The number of repeats is inversely proportional to transcription of the gene. Furthermore, the more the repeats, the more severe the phenotypic change.

A change in the primary structure, the amino acid sequence, of a protein may alter its function (i.e. the quality of the protein). The study of diverse variants of the same protein has greatly advanced the understanding of molecular pathogenetics and given a certain sophistication to the “new” field of endeavor, investigating authentic relationships between genotype and phenotype. This inquiry calls for a new commitment to meaning and the authenticity of the descriptors, matters that are much more sophisticated than the correlations and coefficients that have dominated classic Galton–Fisher theory. The latter may lead to such paradoxical results as that, a nearly perfect correspondence between genotype and phenotype, may nevertheless yield a zero correlation and hence zero heritability. How the quality of a protein can be affected depends, in the first instance, on its normal function.

A mutation can change both quality and quantity of a protein. For example, a change in primary sequence might affect the stability of the protein and lead to enhanced (or retarded) degradation. In some situations, the amount of the mutant protein is crucial to the severity of the phenotype, especially in the dominant-negative scenario detailed later.

Proteins can be classified into three classes based on function: (1) those whose essential functions involve interactions with small molecules, such as enzymes, receptors, and transporters; (2) those that perform regulatory roles, such as transcription factors and hormones; and (3) those that function in complex systems, often in a structural role, and often in association with other proteins. Table 14-4 lists some examples.

Most proteins have one or more domains associated with specific functions. Not surprisingly, proteins in the same class often have domains in common, and there is remarkable conservation of sequences among domains. For example, transcription factors all have one or more amino acid sequence motifs (leucine zipper, zinc finger) that facilitate binding of the protein to DNA sequences. Cellular receptor molecules have domains that enable interaction with the lipid bilayer of the cell membrane, an extracellular domain that binds a ligand, and often

**TABLE 14-4** Classification of Proteins Based on Function

Function	Examples
Interaction with small	Enzymes, channel proteins, molecules transport proteins
Regulation	Peptide hormones, transcriptional regulators, RNA-binding proteins
Structure	Collagens, elastin

a domain that resides in the cytoplasm, perhaps exhibiting kinase activity. Some molecules have many domains, some of which are composed of dozens of repeated motifs—witness fibrillin (see Chapter 153), lipoprotein(a) (see Chapter 96), and plasminogen (see Chapter 54). The conservation of domains has facilitated discovery of the cause of numerous diseases through positional cloning. Thus, when a newly identified open reading frame is sequenced and found to be a strong candidate for the cause of a disorder, generally through identification of a mutation, the logical question is what the function of the protein encoded by the gene might be. If the coding sequence specifies an amino acid motif typical of a zinc finger, the protein is likely to be a transcription factor. This process is aided considerably by large databases that incorporate knowledge of genetic sequences and protein structure and function from both humans and all other organisms.

Proteins that interact with themselves (to form multimers) or with other proteins are subject to enhancement of a pathologic effect when one copy of their gene is mutant. Even though the patient is heterozygous for the mutation, the defective protein, by interacting with the product of its normal allele, or the products of other nonmutant genes, consumes these normal proteins; the result is a much more severe phenotype than would be expected from having half-normal levels of the normal protein. This is termed the dominant-negative effect, and is rather common. The irony is that a “more severe” mutation, such as one that eliminates transcription from the mutant allele altogether (i.e. a null allele), has less effect on phenotype than does a missense mutation that leads to normal transcription and translation of a mutant protein.

Within each of the three classes of proteins, a mutation can have one of four consequences: quantitative increase or decrease in function and qualitative gain or loss of function. Each of these consequences can have a number of molecular explanations (37).

A quantitative increase in function can be due to a regulatory mutation. An example is loss of sensitivity to inhibition, such as by a repressor molecule. A mutation could also affect the active site of an enzyme, such that its  $V_{\max}$  was increased, or the binding site of a hormone, such that the  $K_M$  was lowered. Many disorders associated with expansion of unstable trinucleotide repeats,

such as Huntington disease, share gain-of-function pathogenesis (42).

A quantitative decrease in function could operate by the converse of any of the mechanisms in the previous paragraph. The extreme of the spectrum of decreased function is loss of function, perhaps the easiest to conceptualize, and certainly the most prevalent consequence. For example, most inborn errors of metabolic pathways result from an enzymatic failure. The enzymopathy can be due to a mutation in or around the locus encoding that enzyme, resulting in a qualitative or quantitative defect as described earlier; to abnormal posttranslational processing of the nascent enzyme; to abnormal subcellular localization or extracellular trafficking; to altered affinities for substrates or cofactors; or to altered responsiveness to allosteric regulators of activity. Other examples of loss-of-function phenotypes include familial hypercholesterolemia due to many of the defects in the low-density lipoprotein receptor and cancers due to defects in tumor suppressor genes such as the retinoblastoma or neurofibromatosis type 1 genes. Strains of mice bearing gene “knockouts” represent specified loss-of-function mutations; these are especially popular tools for studying development and neoplasia.

Quantitative and qualitative loss of function clearly overlap. A mutation that reduces the ability of an enzyme to bind substrate also might lead to enhanced degradation and a reduced steady-state amount of the protein molecule.

Mutations that cause a gain in function, that is, a function not intrinsic to the wild-type protein, are less common. The diverse familial amyloidoses are examples, in which a change in amino acid sequence of one or another protein (e.g. transthyretin) results in enhanced stability of the protein and abnormal tissue deposition (see Chapter 79).

The least commonly recognized molecular phenotype, also qualitative, is a change in function. One example is the product of the fusion of the BCR and the ABL genes in chronic myelogenous leukemia (see Chapter 75). Another example is the *p53* protein, which when mutated in some ways, assumes regulatory capabilities foreign to the normal product.

As useful as these protein phenotypes are for classification (and education), there are limitations in making the intellectual leap to the next level of pathogenetic complexity. For example, gene knockout mutations are relatively easy to generate in mice, and increasingly in other species. Many investigators see this technique as a facile way to isolate the physiologic role of a particular gene product, to generate an animal model of a given disease, or to serve as the background strain into which a defined mutation is introduced (43). There is no question that the approach has been brilliantly successful in a number of instances. However, the pitfalls have been underemphasized. For example, some mice homozygous for the absence of transforming growth factor- $\beta_1$

(TGF- $\beta_1$ ) were born normal in appearance and survived, both unexpected results given the prominent role of this cytokine in many aspects of development (44). The reason is “rescue” of the embryo by maternal TGF- $\beta_1$  that presumably crosses the placenta in sufficient quantity to replace the deficient fetal sources. But at a more fundamental level, the “null” mutant animal cannot be viewed as an artificial isolated system focused on that deficient gene product. Rather, the mutant strain is a complex homeostatic system capable of responding to loss of a specific protein, even compensating for it. Thus, if the null strain shows no phenotype, it would be inappropriate to conclude that the missing protein is not important to the physiology of a given system (physiologic or developmental) (45).

The actual effect of the mutation may be loss of function at the protein level, but gain of function at the cellular level. For example, Rett syndrome (OMIM\*312750) is a pleiotropic, severe neurologic disorder that primarily affects girls. The cause is mutation of the *MECP2* locus, which encodes a protein that represses transcription of other genes (46). Mutations that inactivate the *MECP2* protein result in enhanced or inappropriate production of proteins in various tissues, most obviously the brain.

## 14.9 CONCLUSIONS

The prognosis of a disease is largely a matter of pathogenesis. For instance, its age of onset, the rapidity of its course, and the vulnerable points at which disease and complications may occur all depend on details that in principle, as much as in fact, may be difficult to infer even from the most detailed knowledge of the basic defect. Some knowledge of the prognosis may come from “black box” empirical inquiries—the natural history of myotonic dystrophy, for instance—but this course calls for extensive data, and there may be disturbing discrepancies between one study and another that are not readily reconciled. If the pathogenesis is understood, even partially, more incisive methods may be available, including direct measurements of the progress of components of the disease. For instance, the pathogenesis of familial polyposis coli is not clearly established, but currently the course of this disease and its response to treatment are easier to study than Alzheimer dementia. Refined studies at the molecular level make for very precise statements about etiology. It is tempting, but rather treacherous, to view pathogenesis in the same way. But where the concern lies in either the assessment of morbidity or the study of the population and eugenic behavior of the mutant, to attach too much weight to refined biochemistry may push the precision of the statement at the expense of its significance. For the overt clinical pattern and the target of selection are very coarse matters; the many modifying factors, which to the basic scientist are largely a nuisance, may have important attenuating effects on the course of the disorder.

Many advances in therapeutics have resulted from largely empirical reasoning as to choosing an approach, but from an understanding of natural history in judging whether the therapy was successful. A more rational approach to targeting therapy is based on an understanding of pathogenesis. Some fondly held the hope of circumventing “indirect” therapies for genetic disorders by simply replacing the defective gene. But considerable experience has amply shown the general fallacy in this approach. Until the molecular pathogenesis of a disorder is elucidated, the effects of simply adding back, or even replacing, a gene that should have been functioning perhaps from conception will be as empirical as anything physicians had available in the eighteenth century.

## ACKNOWLEDGMENTS

This revision was accomplished during a time of support by the National Heart, Lung and Blood Institute (GenTAC) and the National Human Genome Research Center (Center of Excellence in ELSI Research P50-HG-004487), both of the U.S. National Institutes of Health, and while in residence at the Brocher Foundation, Hermance, Switzerland. The original chapter on which this revision is based owes much to the research and insights of the late Edmond A Murphy, MD, ScD.

### Biography

**Reed Pyeritz** completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

### 15.1 INTRODUCTION AND OVERVIEW

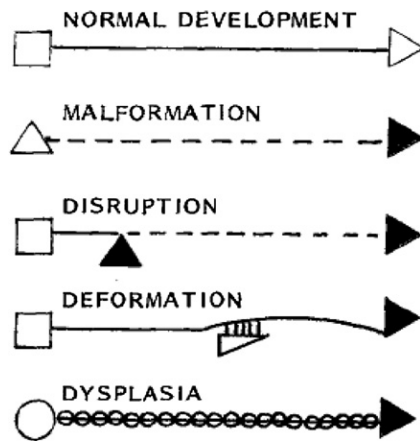

Congenital anomalies in humans can be classified into the following categories, which are defined as follows (1–3) (see Chapter 35 for details):

1. **Malformation:** A defect resulting from an intrinsic abnormality in the development of an organ or region of the body, that is, an error in morphogenesis from the earliest stages of embryogenesis or organogenesis.
2. **Disruption:** A structural defect in an organ, part of an organ, or a region of the body caused by extrinsic interference with, or breakdown of, a normally developing organ during organogenesis; the causes of disruption may be vascular (e.g. interruption of blood supply to developing organ), mechanical (e.g. amniotic bands), or infectious in origin, and the resulting defect does not conform to developmental fields.
3. **Deformation:** An “abnormal form, shape, or position of a part of the body” (1) due to either an extrinsic mechanical force (e.g. intrauterine compression from uterine leiomyomas) or an intrinsic developmental anomaly such as congenital myopathies leading to reduced limb movements in utero and consequently arthrogryposis.
4. **Dysplasia** is the “abnormal organization of cells into tissue(s)” (1) and therefore reflects “dyshistogenesis.” It may affect multiple organ systems that share the same tissue type, and unlike malformations, disruptions, and deformations, the resulting abnormality may change overtime with physical growth in the postnatal period. Examples of dysplasias include skeletal dysplasias and neurocutaneous melanosis sequence (OMIM# 249400) (Figure 15-1).

Malformations may be due to (1) incomplete morphogenesis in which there is either a complete lack

of development of an organ/tissue, or an incomplete developmental process, that is, a “developmental arrest”; (2) aberrant morphogenesis resulting in the presence of a tissue that does not appear in normal morphogenesis; (3) redundant morphogenesis resulting in the presence of accessory or duplicated structures such as polydactyly and preauricular skin tags (3,4).

Much of what we have learned about human development has come from studies in animal models. This is possible because the genes involved in development are highly conserved across species. The most common animal models that have been used are *Caenorhabditis elegans* (roundworm), *Drosophila melanogaster* (fruit fly), *Danio rerio* (zebrafish), *Xenopus laevis* (frog), *Gallus gallus* (chicken), and *Mus musculus* (mouse), although *Xenopus laevis* is tetraploid which renders genetic experiments challenging. However, there are differences in the functions of developmental genes among different animal classes, and even within the same class such as mammals. Recently, it has been shown that Oct4, a transcription factor that is critical for the induction and maintenance of pluripotency in stem cells, is expressed only in the inner cell mass (ICM) in the mouse blastocyst, but it is expressed in both the ICM and the trophectoderm (TE) in the cow blastocyst (5). Differences in patterns of gene expression between human and mouse pre-implantation embryos have also been reported (6). These data suggest that early embryonic development may differ even among placental mammals. Moreover, the phenotypic resemblance of a mutant animal model to the human phenotype depends partly on the genetic background and the presence of modifier genes in the animal model.

**FIGURE 15-1** Schema depicting different types of errors of morphogenesis. The broken line in malformation, disruption, and dysplasia symbolizes the developmental potential, not the time of manifestation of the defect, which may be late in embryogenesis. A dysplasia can be the result of an intrinsic or an extrinsic (disruptive) event. (Spranger, J.; Benirschke, K.; Hall, J. G.; Lenz, W.; Lowry, R. B.; Opitz, J. M.; Pinsky, L.; Schwarzacher, H. G.; Smith, D. W. *Errors of Morphogenesis: Concepts and Terms. Recommendations of an international working group*. J. Pediatr 1982, 100 (1), 160–165.)

## 15.2 TIMING OF NORMAL HUMAN DEVELOPMENT

The development of the human embryo (i.e. embryogenesis), which occurs in the first 8–9 weeks from fertilization to the beginning of the fetal period can be divided into 23 “Carnegie stages” based on work by the embryologist Franklin P. Mall (1862–1917) in the Department of Embryology at the Carnegie Institution of Washington. Carnegie staging of human embryos is based primarily on the “morphologic characteristics” rather than the age or size of the embryo, although each stage corresponds to an approximate post-fertilization/postconception age (NOT gestation age, which begins from the last menstrual period, approximately 2 weeks prior to fertilization in women with regular menstrual cycles) and size in terms of crown-rump length. The Carnegie stages, with the key events at each stage and the approximate post-conception age in days, are shown in Table 15-1 (7).

The first 4 weeks of development, from fertilization until the end of gastrulation (*vide infra*) (i.e. Carnegie stage 13), is also known as *blastogenesis*. Organogenesis begins at the end of blastogenesis and is characterized by morphogenesis (formation of organs and other body parts) and histogenesis (differentiation of cells and tissues) (8). The fetal period, which begins after Carnegie stage 23 and continues through delivery, is the period of continuing growth and differentiation of the organs formed during embryogenesis; the fetus also grows rapidly in length and weight during this period.

Knowledge of the timing of organ development helps us understand the latest gestational age at which a genetic or teratogenic “insult” could have occurred.

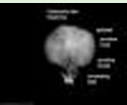

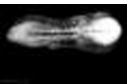

Table 15-2 lists some of the malformations that might result from incomplete morphogenesis and the timing at which those malformations could have occurred (9). In general, errors in morphogenesis that occur earlier in development result in more severe malformations than those that occur later in development.

## 15.3 THE CONCEPT OF DEVELOPMENTAL FIELDS AND FIELD DEFECTS

Morphogenesis is believed to occur within developmental fields, defined as “a region or a part of an embryo which responds as a coordinated unit to embryonic interaction and results in complex or multiple anatomic structures” (1). The *primary field*, which comprises the entire early embryo, is established through blastogenesis. The primary field is then subdivided through the process of pattern formation into *progenitor fields*, which give rise to the primordia of all morphologic structures. Subsequent differentiation results in *secondary* or *epimorphic fields*, which form the “irreversibly determined final structure(s).” Histogenesis occurs much later in development, usually after pattern formation. As such, most organs that are malformed are histologically normal and not at risk of developing malignancies; on the other hand, abnormal histogenesis in a dysmorphogenetic organ might result in malignancy.

Abnormal differentiation during organogenesis usually leads to a *monotopic field defect* and hence an anomaly in a single structure or organ. In contrast, abnormal blastogenesis usually results in a *polytopic field defect* in which multiple structures/organs in different parts of the body that share the same primary developmental field are malformed. Multiple congenital anomalies may also be part of a *sequence*, defined as “a pattern of multiple anomalies derived from a single known or presumed prior anomaly or mechanical factor”—it refers to a “cascade of consequences with known pathogenetic mechanisms”; a *syndrome*, defined as “a pattern of multiple anomalies thought to be pathogenetically related and not known to represent a single sequence or a polytopic field defect”; or an *association*, defined as “a non-random occurrence in two or more individuals of multiple anomalies not known to be a polytopic field defect, sequence, or syndrome [...] refers solely to statistically, not pathogenetically or causally related anomalies” (1,10). It has been suggested that the term “association” be limited to the “the idiopathic statistical occurrence of multiple congenital anomalies apparently of non-blastogenetic origin.” Hence, the VATER “association” (OMIM# 192350), which is postulated to be due to a blastogenetic defect, should be considered a polytopic field defect instead of an association (10). Similarly, the CHARGE “association” became the CHARGE syndrome (OMIM# 214800) when *CHD7* was identified as the causative gene in this condition.

## 15.4 CELLULAR SIGNALING IN DEVELOPMENT: THE CONCEPTS OF INDUCTION AND COMPETENCE

Cellular differentiation and organ formation are dependent on interactions between cells and tissues of different origins that are in close proximity to each other. This type of interaction is known as *induction*. The tissue that releases the signal is known as the inducer, while the “target tissue” is known as the responder. For a tissue to be a responder, it has to possess the appropriate receptor for the signaling molecule, as well as *competence*, which is defined as the ability of the tissue to respond to a specific signal; not all tissues are competent to respond to a specific signal from a specific inducer. For example, in the development of the lens in *Xenopus*, only the anterior ectoderm (i.e. ectoderm in

the head) is competent to be induced by the optic vesicle. However, an initial induction may result in a specific tissue becoming competent to respond to signals from a subsequent inducer. Moreover, once induction has occurred, the responder may then induce its own inducer, a phenomenon known as *reciprocal induction*. Examples of induction include the interactions between the epidermis of the skin or epithelium of the intestines (both derived from ectoderm) and the underlying dermis or mesenchymal tissue (both derived from mesoderm) respectively. Induction may be “region-specific” such that the structures derived from the responder may be dependent on the region from which the inducer was derived. For example, the cutaneous structures that develop from the epidermis (responder) depend partly on the source of the dermal mesenchyme (inducer) (11).

**TABLE 15-2 Developmental Pathology of Certain Malformations Which Represent Incomplete Development**

Tissues	Malformation	Defect in—	Cause prior to—	Comment
Central nervous system	Anencephalus	Closure of anterior neural tube	24 days	Possibility also that origin may be after closure 80% lumbosacral
	Meningomyelocele	Closure in a portion of posterior neural tube	26 days	
Face	Cleft lip	Fusion of lateral and median nasal processes	36 days	42% associated with cleft palate
	Cleft maxillary palate	Fusion of maxillary palatal shelves	8 weeks	Preauricular and along line of anterior sternocleidomastoid
	Branchial sinus and/or cyst	Resolution of branchial cleft	8 weeks	
Gut	Esophageal atresia + tracheo-esophageal fistula	Lateral septation of foregut into trachea and foregut	30 days	Associated incomplete or aberrant mesenteric attachments
	Rectal atresia with fistula	Lateral septation of cloaca into rectum and urogenital sinus	6 weeks	
	Duodenal atresia	Recanalization of duodenum	7–8 weeks	
	Malrotation of gut	Rotation of intestinal loop so that cecum lies to right	10 weeks	
	Omphalocele	Return of midgut from yolk sac to abdomen	10 weeks	May contain gastric and/or pancreatic tissue
	Meckel's diverticulum	Obliteration of vitelline duct	10 weeks	
	Diaphragmatic hernia	Closure of pleuro-peritoneal canal	6 weeks	
Genital-urinary system	Extroversion of bladder	Migration of infraumbilical mesenchyme	30 days	Associated Müllerian and Wolffian duct defects
	Renal agenesis	Genesis of ureter from mesonephric duct	30 days	
	Bicornuate uterus	Fusion of lower portion of Müllerian ducts	10 weeks	
	Hypospadias	Fusion of urethra (labia minora) folds	12 weeks	
	Cryptorchidism (of testicle)	Descent of testicle into scrotum	7–9 months	
Heart	Transposition of great vessels	Directional development of bulbus cordis septum	34 days	
	Ventricular septal defect	Closure of ventricular septum	38 days	
	Patent ductus arteriosus	Closure of ductus arteriosus	9–10 months	
Limb	Aplasia of radius	Genesis of radial bone	38 days	Often accompanied by other defects of radial side or distal limb
Complex	Syndactyly	Separation of digital rays	42 days	Secondary defects of mid-face and forebrain Associated defects of cloacal development
	Cyclopia, holoprosencephaly	Prechordal mesoderm development	26 days	
	Sirenomelus, symphodia	Development of posterior axis	26 days	

Induction is often mediated by *paracrine factors*, which are signaling proteins that are secreted by a group of cells (i.e. the inducer) and diffuse across relatively short distances in the intercellular space to alter the differentiation or “behavior” of neighboring cells (i.e. the responder); this is known as a paracrine interaction. In contrast, *endocrine factors* (i.e. hormones) have to travel through the blood stream across relatively long distances to their receptors. Induction

may also be mediated through *juxtacrine signaling* or interactions in which cell membrane proteins on the inducing cell interact directly with the receptors on the adjacent responding cell. Almost all of these interactions lead to a series of enzymatic reactions in the responding cell that result in either the regulation of transcription factors and hence gene expression, or the regulation of cytoskeletal structures and hence cell shape or motility (11).

## 15.5 A LIMITED REPERTOIRE OF DEVELOPMENTAL GENES AND PATHWAYS

Embryogenesis and the development of various organ systems utilize a common set of genes and developmental pathways. The same gene may be expressed in different tissues at different developmental stages or regulate different developmental pathways and hence affect the development of different organ systems. Some developmental pathways interact with one another. There are also parallel pathways leading to “redundancy” due to the presence of paralogous genes (i.e. genes with very similar nucleotide sequences and are presumably derived from the same ancestral gene by gene/chromosome duplication) (3). For example, the Hox (homeobox) gene families are responsible for the determination of the anterior–posterior axis and patterning of the axial skeleton in all vertebrates. All mammals have four Hox gene clusters (*Hoxa*, *Hoxb*, *Hoxc*, *Hoxd*) on different chromosomes that arose from duplications of each ancestral Hox gene cluster such that the equivalent Hox gene in each cluster is paralogous with one another, although not every Hox gene is present in each cluster (e.g. the Hox1 paralogous group comprises *Hoxa1*, *Hoxb1*, and *Hoxd1*—*Hoxc1* does not exist in mammals; the Hox4 paralogous group comprises *Hoxa4*, *Hoxb4*, *Hoxc4*, and *Hoxd4*) (11). It was found that mutations in all six alleles of the three Hox10 paralogous genes in the mice (*Hoxa10*, *Hoxc10*, *Hoxd10*) resulted in a complete lack of lumbar vertebrae, abnormal sacral vertebrae, and ectopic ribs, but mutations in any five of the six alleles resulted in a far less severe phenotype with the preservation of the lumbar vertebrae. More importantly, the phenotypes of these “five allele mutants” mice were similar regardless of the allele that was mutated, demonstrating the redundancy among the Hox10 paralogous genes. Similar findings were reported for the Hox11 paralogous genes when those complete “triple mutants” mice were compared with mice harboring mutations in five out of the six Hox11 paralogous alleles (12).

## 15.6 STEPS AND CONCEPTS IN EMBRYONIC DEVELOPMENT

Following the fertilization of the mammalian oocyte by the spermatozoa in the ampulla of the oviduct, meiosis II in the oocyte is completed, the pronuclei of the oocyte and spermatozoa fuse, and about 24–27 hours later, the diploid *zygote* undergoes the first *cleavage* (i.e. mitosis without synthesis of cytoplasm and hence without an increase cellular mass) to form two *blastomeres* (i.e. early embryonic cells formed by through mitosis of the zygote). Subsequent cleavage results in the formation of a “solid” *morula* with 12–15 cells by day 4 post-fertilization, comprising a collection of cells that will form the inner cell mass *ICM* surrounded by an external layer of cells (*trophoblast*) that will form the trophectoderm *TE*. The ICM will give rise

to the embryo while most of the cells of the TE will form the chorion, which is the embryonic component of the placenta (11,13). The TE is the first type of cells to differentiate in mammalian development, and it is required for the subsequent formation of the blastocoel (*vide infra*) (14).

Mammalian cleavage is asynchronous in that not all blastomeres undergo mitosis at the same time. Consequently, there can be an odd number of blastomeres in the embryo. Maternal mRNA that is present in the oocyte at the time of fertilization may be translated either before or after fertilization, and these maternally derived proteins regulate the development of the zygote in the earliest stages. In the human embryo, the zygotic genes are first expressed at around day 3 post-fertilization between the four-cell and eight-cell stages (3). It is believed that this maternal–zygotic transition is regulated by microRNAs miR-302, miR-372, and miR-516–520, which are the human orthologs of the zebrafish miR-430 cluster (15). Cleavage and development is therefore regulated from a relatively early stage by zygotic rather than maternally inherited proteins.

Following the third cleavage (eight-cell embryo) at approximately day 4 post-fertilization just prior to the formation of the morula, the blastomeres which had hitherto had a “loose configuration,” aggregate tightly together in a process known as *compaction* due to the expression of cell adhesion proteins such as E-cadherin (*CDH1*). Homozygous *Cdh1* mutations in mouse embryonic stem cells resulted in embryos that failed to maintain compaction and were incompatible with life, but embryonic stem cells with heterozygous *Cdh1* mutations appeared to develop normally (16).

The earliest blastomeres, which have the potential to become either the ICM or the trophoblast, are *totipotent* (i.e. capable of everything), while the cells of the ICM can form any tissue in the fetus but not those of the TE such as the chorion, and hence are considered *pluripotent* (i.e. capable of many things). *Cell fate* refers to the type of cell that an undifferentiated embryonic cell would normally develop into. Commitment of a cell to a specific cell fate is initiated by the potentially reversible process of specification followed by the generally irreversible process of determination. Cells in most vertebrates undergo *conditional specification* in which the fate of a given cell is dependent on paracrine factors secreted by the neighboring cells. The fate of a cell may also be specified by the concentration of morphogens, which may be paracrine factors secreted by a group of cells externally or transcription factors within the cell; a given cell may have different fates depending on the concentration of the morphogen it is exposed to. *Determination* is said to have occurred when a cell differentiates into its original (intended) cell fate even when it is experimentally placed in another region of the embryo (11).

The timing of when the blastomeres are first determined to become the ICM and the trophoblasts remains somewhat controversial, but it is generally believed to occur after the formation of the morula. Cavitation, the process

**FIGURE 15-2** Human blastocyst hatching from zona pellucida (embryoblast=ICM). (Hill, M. A. *UNSW Embryology*. <http://php.med.unsw.edu.au/embryology/> (Accessed March 18, 2012).)

in which the TE cells secrete fluid into the morula itself to form a blastocoel, occurs at approximately day 5 post-fertilization (about a day after compaction) and results in the formation of the blastocyst. As the blastocoel expands, the ICM is “pushed” to one side of the blastocyst and becomes a separate layer from the TE by the 64-cell stage, although it continues to secrete proteins that stimulate the trophoblasts to divide (11). Meanwhile, at approximately days 6–7, the ICM differentiates into the epiblast and the hypoblast (also known as the primitive endoderm); the hypoblast is the outermost layer of cells that overlies the epiblast (Figure 15-2). The epiblast gives rise to all embryonic lineages and the extraembryonic mesoderm, and is hence considered pluripotent; the hypoblast gives rise to the parietal

endoderm and visceral endoderm (VE) (14). The epiblast and hypoblast together form the bilaminar embryonic disc (also known as bilaminar blastoderm), thereby establishing the dorsal–ventral axis of the embryo with the epiblast being the dorsal surface and the hypoblast being the ventral. As these two layers differentiate, a basement membrane is formed between them (18).

### 15.6.1 Hatching and Implantation

The unfertilized oocyte is surrounded by the zona pellucida, an extracellular glycoprotein matrix that is critical for sperm binding during fertilization. After fertilization, the zona pellucida continues to encase the early developing embryo to prevent it from adhering to the wall of the oviduct, which could result in an ectopic pregnancy. However, when the blastocyst reaches the uterine cavity, it has to “hatch” from the zona pellucida, a process that may be mediated by the secretion of a trypsin-like protease by the trophoblasts (see Figure 15-2). The hatched blastocyst attaches itself to the uterine endometrium, initially through L-selectin molecules on the trophoblast cells and subsequently through other adhesion systems involving integrins, P-cadherins, heparan sulfate proteoglycans, and many other cell adhesion molecules (11). Some of the genes and adhesion proteins involved in implantation are reviewed in (19) and (20). The endometrium is receptive to implantation by the blastocyst only within a 48-hour window, about 7–10 days after ovulation (not fertilization). This whole process from fertilization to implantation is illustrated in Figure 15-3.

**FIGURE 15-3** Development of the preimplantation blastocyst in humans. Adapted from Reference (17) figure copyright: Terese Winslow (<http://teresewinslow.com/>).

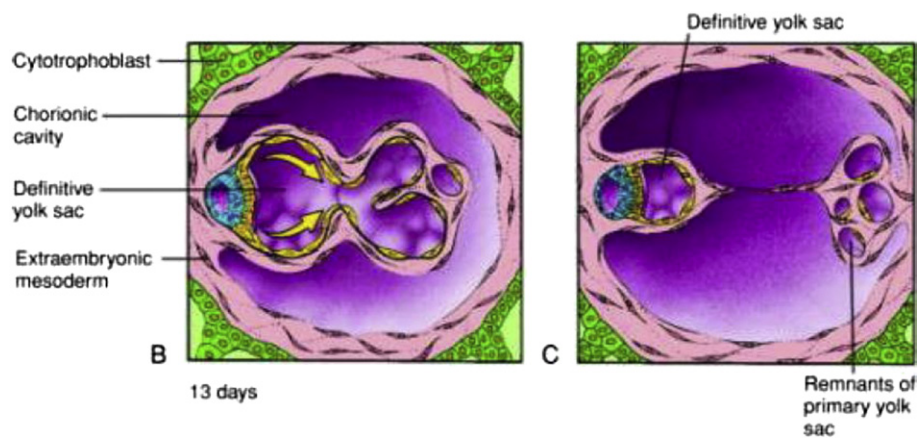

### 15.6.2 Formation of the Amniotic Cavity and Yolk Sac

At approximately day 8 post-fertilization, an amniotic cavity forms within the epiblast, resulting in the bilaminar embryonic disc becoming sandwiched between the amniotic cavity dorsally and the blastocyst cavity ventrally. The epiblast cells surrounding the amniotic cavity form an extraembryonic membrane known as the amnion. Cells from the hypoblast then migrate to form an exocoelomic (Heuser's) membrane around the blastocyst cavity, which becomes the primary yolk sac. Meanwhile, the trophoblast differentiates into a cellular cytotrophoblast and an expanding syncytiotrophoblast (a multinucleate cytoplasmic mass that arises from a loss of plasma membrane and mitosis without division of cytoplasm), both of which contribute to the eventual formation of the placenta (18) (Figure 15-4).

The extraembryonic mesoderm forms around day 10 and fills the space between the exocoelomic membrane and the cytotrophoblast; it is believed that the extraembryonic mesoderm is derived from cells in the hypoblast and primary yolk sac. The extraembryonic mesoderm continues to expand and fills the space between the amnion and the cytotrophoblast by day 12. The extraembryonic mesoderm overlying the blastocyst cavity then “splits” to form the chorionic cavity (also known as extraembryonic coelom), which expands to surround the primary yolk sac, the bilaminar embryonic disc, and the amniotic cavity, except at the connecting stalk, which is the part of the extraembryonic mesoderm that suspends the developing embryo in the chorionic cavity. A second wave of migration of hypoblast cells displaces the primary yolk sac to form the secondary (definitive) yolk sac; the primary yolk sac eventually degenerates by day 13 (18) (Figure 15-5).

**FIGURE 15-4** Day 9 embryo implanted in endometrium (18). (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H., Larsen's Human Embryology, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

**FIGURE 15-5** On days 12 and 13, a second wave of migration of hypoblast cells produces a new membrane that migrates out over the inside of the extraembryonic mesoderm, pushing the primary yolk sac in front of it. This new layer becomes the endodermal lining of the secondary (definitive) yolk sac. (B and C) As the definitive yolk sac develops on day 13, the primary yolk sac breaks up and is reduced to a collection of vesicles at the abembryonic end of the chorionic cavity. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. Larsen's Human Embryology, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

### 15.6.3 Gastrulation, Segmentation, and Formation of Body Axes

At approximately day 15, epiblast cells proliferate and migrate to the mid-sagittal plane in what will become the more caudal part of the of the bilaminar embryonic disc to form the primitive streak. The primitive streak then elongates along the sagittal plane and a narrow primitive groove develops within the primitive streak. The cranial end of the primitive streak expands to form the primitive node, within which is a small depression known as the primitive pit. Epiblast cells then migrate toward the primitive streak where *epithelial-to-mesenchymal transformation (or transition)* (EMT) occurs, a process in which the epiblast cells become less regularly shaped (often “flask-shaped”) and less tightly connected with one another, i.e., becoming mesenchymal in nature. These transformed epiblast cells invade and displace the hypoblast, eventually replacing it with a new layer of cells known as the definitive (embryonic) endoderm. Beginning around day 16, the invaginating (or ingressing) mesenchymal epiblast cells enter the space between the epiblast and the hypoblast/endoderm to form the intraembryonic mesoderm (Figure 15-6). Once the definitive endoderm and intraembryonic mesoderm have been formed, the remaining epiblast cells become the ectoderm. The formation of all three germ layers from epiblast cells, resulting in the trilaminar embryonic disc, constitutes gastrulation (18).

In an area just cranial to the primitive streak, the ectoderm forms a mild depression and fuses with the endoderm without the mesoderm to form a bilaminar membrane known as the oropharyngeal membrane, which eventually ruptures during the fourth week of development to form the opening of the mouth; a similar bilaminar membrane—the cloacal membrane, which eventually gives rise to the openings of the anus, the urinary and genital tracts—is formed caudal to the primitive streak. At around day 17, a subpopulation of mesodermal cells migrates cranially from the primitive

node to form the hollow notochordal process, which is subsequently transformed into a solid notochord by day 22, as illustrated in Figures 15-7 and 15-8. The notochord is responsible for the induction of vertebral bodies (18).

A subpopulation of mesodermal cells becomes the paraxial mesoderm and flanks the notochord on each side (Figure 15-8). In the region that will eventually become the head, these mesodermal cells form “bands of cells” that remain unsegmented and form the head mesoderm; in the region that will become the trunk, the column of paraxial mesoderm on each side of the notochord, known as the presomitic mesoderm, forms “bands of cells” that segment into blocks known as somites in a cranial–caudal direction, starting at the head–trunk junction on day 20 and lasting through day 30 when about 42–44 pairs of somites are eventually formed. The most caudal somites subsequently regress, leaving about 37 pairs of somites. These somites give rise to the occipital bone of the skull, the spine, and the skeletal muscles of the neck, trunk, and limbs. The first four pairs of somites contribute to the formation of the occipital skull bone, the bones of the mid-face and the inner ear, and the muscles of the tongue. The remaining somites form the vertebrae, skeletal muscles, and dermis of the cervical, thoracic, lumbar, and sacral spine; the three most caudal somites are the coccygeal somites that form the coccyx. Immediately lateral to the somites is the intermediate mesoderm, which also forms segments, and lateral to the intermediate mesoderm is the unsegmented lateral plate mesoderm (18) (Figure 15-9).

The formation of the primitive streak establishes the major body axes. Since the primitive node/pit lies at the cranial end of the primitive streak, the primitive streak defines the cranial–caudal axis. With the primitive streak being in the midline (i.e. most medial), the medial–lateral axis is thereby defined. When viewed from within the amniotic cavity, the midline primitive streak divides the embryo into the right and the left sides, hence defining

**FIGURE 15-6** (A) On days 14 and 15, ingressing epiblast cells displace hypoblast and form definitive endoderm. (B) Epiblast that ingresses on day 16 migrates between endoderm and epiblast layers to form intraembryonic mesoderm. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

**FIGURE 15-7** Formation of the notochordal process. (A and C) Stages showing hollow notochordal process growing cranially from the primitive node. Note changes in relative length of the notochordal process and primitive streak as the embryo grows. Also note, fusion of ectoderm and endoderm in the oropharyngeal and cloacal membranes. (B) Cross section of the embryonic disc at the level indicated by the dotted lines. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

**FIGURE 15-8** The process by which the hollow notochordal process is transformed into a solid notochord between days 16 and 22. (A and B) First, the ventral wall of the notochordal process fuses with the endoderm and the two layers break down, leaving behind the flattened notochordal plate. As shown in (B), this process commences at the caudal end of the notochordal process and proceeds cranially (the dotted line marks the level of (A)). An open neurenteric canal is briefly created between the amniotic cavity and the yolk sac cavity. (C) Series of events by which the notochordal process becomes the notochordal plate and then the notochord. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

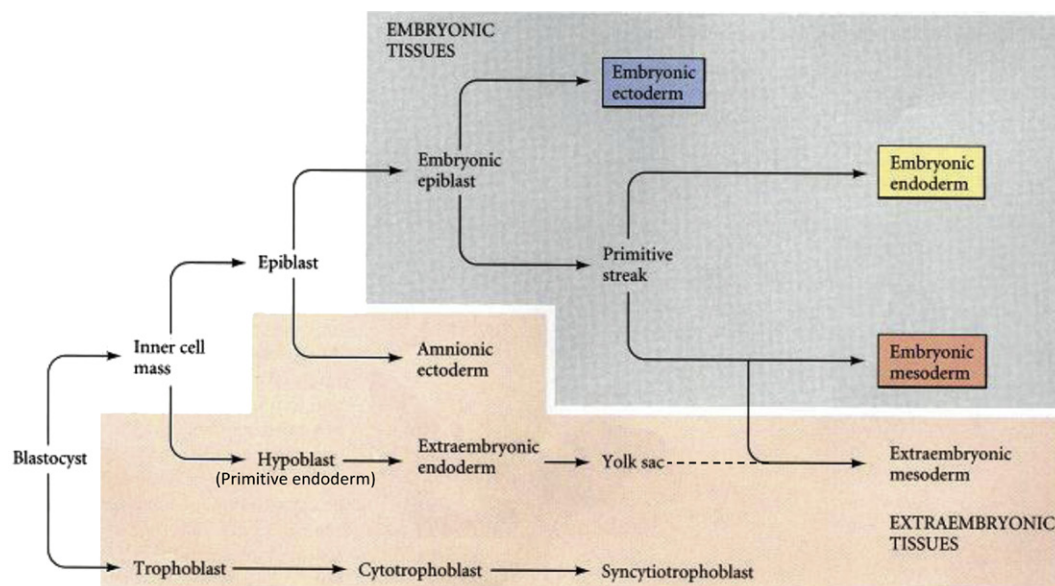

**FIGURE 15-9** Scanning electron micrograph of the trunk region of a chick embryo with the surface ectoderm partially removed to show the underlying neural tube and mesoderm (cranial is toward the top). Note the somites and, more caudally, the paraxial mesoderm that have not yet segmented. Lateral to the somites, the mesoderm has been subdivided into the intermediate mesoderm and lateral plate mesoderm (somatic mesoderm, the layer just deep to the surface ectoderm, is visible). (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

the left–right axis. The early ectoderm–endoderm axis that is established with gastrulation before body folding defines the future dorsal–ventral axis (Figure 15-10).

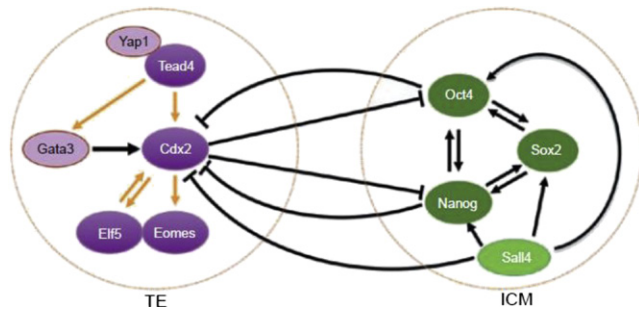

### 15.6.4 Genes and Transcription Factors in Embryogenesis

The homeodomain (also known as homeobox) transcription factors Oct4 (also known as either Pou5f1 [UniProt recommended name] or Oct3) and Nanog that confer pluripotency are initially expressed in all early blastomeres but are subsequently expressed only in the ICM. The transcription factors Cdx2 and Tead4 are required for the initial commitment of the blastomeres to trophoblasts, while Eomes (Eomesodermin homolog) and Elf5 strengthen the commitment of the cells to becoming the trophoblasts. It is now thought that maternally derived Cdx2 that was present in the early zygote is also required for the initial commitment and polarization of the blastomeres into TE. These transcription factors, in turn, are regulated by several other factors, and they cross-regulate each other as well (Figures 15-11 and 15-12). Yap1 is a Tead4 cofactor that, when unphosphorylated, localizes to the nuclei of the outer cells, and the binding of Yap1 to Tead4 in those cells results in the transcription of zygotic *Cdx2* and other trophoblastic genes, thereby committing those cells to the TE lineage. Oct4 is required for the determination of the ICM; Nanog is critical for pluripotency and is required for the formation of the epiblast; Sall4 is required for the differentiation of the ICM into the epiblast and the primitive ectoderm. An HMG-box transcription factor, Sox2, heterodimerizes with Oct4 and promotes the binding of Oct4 to its target genes. Oct4 and Cdx2 bind to each other's promoter to

**FIGURE 15-10** Schematic diagram showing the derivation of tissues in human and rhesus monkey embryos. The dashed line indicates a possible dual origin of the extraembryonic mesoderm. (Gilbert, S. F. *Developmental Biology*, 9th ed., Sinauer Associates, Inc.: Sunderland, MA, 2010.)

**FIGURE 15-11** Molecular mechanisms for the ICM/TE segregation: The regulatory network of key transcription factors in ICM/TE specification. Cdx2, Tead4, Eomes, and Elf5 are the major TE-specific transcription factors. Tead4 cooperates with Yap1 to activate Cdx2, which in turn upregulates Eomes and Elf5. Conversely, Elf5 is able to enhance Cdx2 expression. In addition, GATA3 directly binds to the intron 1 region of the Cdx2 locus and activates Cdx2 expression. In contrast, Oct4, Nanog, and Sox2 form a core regulatory circuitry to promote ICM cell fate. Sall4 not only activates Oct4, Nanog, and Sox2 but also suppresses Cdx2 expression, and this is critical to the differentiation of the ICM and the TE. (Chen, L.; Wang, D.; Wu, Z.; Ma, L.; Daley, G. Q. *Molecular Basis of the First Cell Fate Determination in Mouse Embryogenesis*. *Cell Res.* 2010, 20 (9), 982–993.)

**FIGURE 15-12** Two signaling pathways, the Hippo and MAPK pathways, are involved in the ICM/TE cell fate determination. In inside cells, Lats in the Hippo pathway phosphorylates Yap1, resulting in cytoplasmic distribution of Yap1. Without nuclear Yap1, Tead4 is unable to activate Cdx2. Thus, these cells develop to the ICM. In contrast, due to the inactive Hippo pathway in outer cell, Yap1 remains unphosphorylated and is localized in the nucleus. Yap1 cooperates with Tead4 to activate Cdx2, promoting the TE fate. Erk2 in the MAPK pathway activates Cdx2 and suppresses Nanog, facilitating the TE formation. The mechanisms for Erk2 regulating Cdx2 and Nanog, and the events upstream of Hippo and Erk2, remain unknown. (Chen, L.; Wang, D.; Wu, Z.; Ma, L.; Daley, G. Q. *Molecular Basis of the First Cell Fate Determination in Mouse Embryogenesis*. *Cell Res.* 2010, 20 (9), 982–993.)

suppress each other's transcription, so the cells will differentiate into either the ICM or trophoblasts (11,21).

By the time the ICM has differentiated into the epiblast and the primitive ectoderm, Nanog is expressed exclusively (22) in the epiblast, while the zinc finger transcription factor Gata6 is expressed specifically in, and is required for the development of, the hypoblast (Figure 15-13). Of note, recent studies suggest that signals from properly specified epiblasts are also required

**FIGURE 15-13** The hypoblast and the epiblast lineages in the mouse embryo segregate from the ICM at the blastocyst stage. At E3.5, the ICM shows mosaic and random “salt and pepper” expression of the transcription factors Nanog and GATA6. GATA6-positive cells are subsequently sorted to the distal surface of the ICM, where they give rise to the hypoblast. Nanog-positive cells exclusively give rise to the pluripotent epiblast, the founder tissue of the embryo proper. (Arnold, S. J.; Robertson, E. J. *Making A Commitment: Cell Lineage Allocation and Axis Patterning in the Early Mouse Embryo*. *Nat. Rev. Mol. Cell Biol.* 2009, 10 (2), 91–103.)

for the specification of the hypoblast; hence, Nanog is also indirectly involved in the specification of the hypoblast. It has been suggested that the expression of Gata6 is induced by the activation of the RTK–MAPK (mitogen-activated protein kinase) pathway (*vide infra*) via FGF (fibroblast growth factor) and Grb2; this process also appears to inhibit the expression of Nanog. Recently, it has been found that Sox17 promotes the expression of Gata6 and Gata4, and all three proteins are required for the differentiation of the ICM into the hypoblast. In addition, microRNAs have been found to suppress the transcription of specific pluripotency factors such as OCT4, SOX2, and KLF4 in human embryonic stem cells, which suggests that microRNAs may be important in regulating the differentiation of the ICM (14,23,24).

### 15.6.5 Epigenetics in Early Embryogenesis

Epigenetic changes regulate the pluripotency of the ICM and the epiblast and prevent their differentiation into TE. Soon after fertilization, the paternal genome is actively and rapidly demethylated before the first cell division while the maternal genome undergoes a much slower passive demethylation that lasts through at least the four-cell stage; however, the differentially methylated imprinting control regions are not demethylated. This demethylation leads to the transcription of zygotic Oct4 and Nanog. “Epigenetic modifiers” including various methyltransferases and demethylases then maintain the pluripotent-inducing genes, Oct4, Nanog, Sall4, and Sox2 in an active state, which ensures that the ICM and epiblast remain pluripotent. However, for subsequent differentiation to occur, these pluripotent-inducing genes have to be silenced by various repressors such as transcription factors and methyltransferases (e.g. repression of Oct4 by the EMHT2-EMHT1 methyltransferase

complex). Similarly, *Elf5* is methylated in the ICM and the epiblast, leading to a reduction in the levels of *Cdx2* and *Eomes*, thereby preventing their differentiation into TE (14,23).

### 15.6.6 Genes Involved in Gastrulation, Segmentation, and Axes Formation

Activation of the Wnt signaling pathway leads to competence in the posterior part of the embryo that enables the primitive streak to be formed. Gastrulation is initiated by members of the TGF- $\beta$  superfamily including Nodal. Signaling by Nodal and specific FGFs such as FGF8 induce the epiblast cells to “de-epithelialize” to form the primitive streak and to ingress so as to form the mesoderm and endoderm. There are four FGF8 isoforms in humans (FGF8a, FGF8b, FGF8e, and FGF8f), generated by alternative splicing of exon 1, each of which has a different role in development, but some isoforms may have overlapping roles. For example, experiments in mouse models suggest that although *Fgf8b* is responsible for both gastrulation and development of the midbrain and hindbrain, the presence of *Fgf8a* can partially compensate for the loss of *Fgf8b* in the gastrulation process but not in the development of the midbrain and hindbrain (25). This may explain the diversity of clinical phenotypes arising from loss-of-function mutations in *FGF8* such as gonadotropin-releasing hormone (GnRH) deficiency leading to either idiopathic hypogonadotropic hypogonadism (OMIM# 146110) or Kallman syndrome (hypogonadotropic hypogonadism with anosmia) (OMIM# 612702) (26,27), holoprosencephaly (28), and at least in mouse models, abnormal lung development (29).

Gastrulation also requires *SNAI1*, *SNAI2*, and *SNAI3*; the expression of *SNAI1*, *SNAI2*, and probably *SNAI3*, are induced by members of the TGF- $\beta$  superfamily and maintained by FGF signaling (30). The *SNAI* proteins are zinc finger transcription factors that are the human orthologs of the *Drosophila* Snail protein family. *SNAI1* represses the expression of E-cadherin, which is one of the cell adhesion proteins responsible for compaction of the blastomeres (*vide supra*); *SNAI2* promotes EMT (Figure 15-14); the functions of *SNAI3* have not been well characterized but its amino acids share more than 40% identity with *SNAI1* and *SNAI2*. Many other transcription factors such as the T-box transcription factor, *EOMES*, and the basic helix-loop-helix transcription factors, *MESP1* and *MESP2*, are required for the various cellular processes in gastrulation. Some of these processes and genes are reviewed in (30) and (22).

*SNAI2* is required for the migration and survival of melanoblasts, and as expected, *Snai2*-null mice have been found to have areas of depigmentation on their skin as well as a “white forehead blaze” among other characteristics consistent with the expression of *Snai2* in the developing mesenchymal tissues of the skull/face, lungs, kidneys, and intestines (31). Homozygous deletions in *SNAI2* have been

reported in 2 out of 38 unrelated individuals with Waardenburg syndrome type 2 (OMIM# 608890), characterized by sensorineural hearing loss and heterochromia irides (32). Heterozygous deletions in *SNAI2* have been reported in 3 out of 17 unrelated individuals with piebaldism (OMIM# 172800) who were negative for *KIT* mutations; all three of these individuals had patchy hypopigmentation in all of their bodies (33). However, in a more recent study with 30 Waardenburg syndrome type 2 subjects, no *SNAI2* mutations or deletions were identified (31).

The “clock and wavefront” model underlies the molecular basis of somitogenesis. In this model, the transcription of specific genes in the Notch signaling pathway such as *HES7* (hairly and enhancer of split 7 (*Drosophila*)), *LFNG* (lunatic fringe), and *DLL3* (delta-like 3) in the presomitic mesoderm oscillates (i.e. cycles) due to negative feedback loops between the Notch and the Wnt signaling pathways, and these cells are competent to form somites only when the expression of these genes is in a specific phase; this is the “segmentation clock,” and the oscillating expression of these genes recycles and spreads continually from the caudal to cranial direction (Figure 15-15). Meanwhile, *FGF8* is expressed by cells in the tail bud as the embryo elongates caudally but *FGF8* expression decays overtime such that its expression is lowest in the most cranial, and highest in the most caudal, presomitic mesoderm; in essence, this creates a “wavefront” of *FGF8* expression that moves from the cranial to caudal direction. In addition, expression of *ALDH1A2* (also known as *RALDH2* (retinaldehyde dehydrogenase 2)), a gene that is required for the synthesis of retinoic acid (RA), is higher in the newly formed somites. This thereby creates an increasing gradient of RA, which antagonizes *FGF8* signaling and activates genes required for somitogenesis such as *MESP1* and *MESP2*, from the previously formed somites into the more caudal presomitic mesoderm. High levels of *FGF8* inhibit somitogenesis. Therefore, somites are formed only when both the expression of the segmentation clock genes are in a specific phase and *FGF8* expression is below a certain threshold—this forms the “determination front” in somitogenesis (18,34,35). Recently, it has been suggested that the wavefront includes the expression of both *FGF8* and *FGF4* (36).

It is interesting that homozygous or compound heterozygous loss-of-function mutations in *DLL3*, *MESP2*, *LFNG*, and *HES7* cause autosomal recessive spondylocostal dysostosis types 1 to 4 (OMIM# 277300, 608681, 609813, 613686), respectively. However, most *MESP2* mutations have resulted in spondylothoracic dysostosis, instead of spondylocostal dysostosis, in which a homozygous *MESP2* mutation has been reported in only one family (37). It is notable that as discussed above, *DLL3*, *LFNG*, and *HES7* are all part of the segmentation clock, while *MESP2* is critical for somitogenesis, including determining the polarity of somites. Spondylocostal

dysostosis is characterized by the presence of multiple contiguous segmentation defects of the vertebrae resulting in a short neck and short trunk, rib anomalies, and small thoracic cavity especially in neonates. Spondylo-thoracic dysostosis has a similar but more severe phenotype resulting in a shorter spine and greater risk for respiratory insufficiency in infancy (38,39).

Studies on the genetics and development of left–right asymmetry have been complicated by the findings that the homologous left–right organizers in the different vertebrate species have different ultrastructures, initiate left–right determination differently, and mutations in homologous genes can result in vastly different phenotypes in different species, even among mammals. Our understanding of left–right determination has been based

on studies in vertebrate animal models including mice, rabbits, chickens, frogs (*Xenopus*), and zebrafish, but how well these models reflect the mechanism of left–right determination in the human embryo is unclear. Nevertheless, some basic developmental principles appear to be common to many species.

It is believed that left–right asymmetry is first established in the primitive node, which is homologous to the ventral node in the mouse, the Hensen's node in the chicken, and the dorsal lip of the blastopore in *Xenopus*. The cells at the center of the node have a motile cilium (known as monocilium) each. Each monocilium is made up of a ring of nine microtubule doublets, each with an inner and an outer dynein arm; unlike cilia in other cells, there are no central microtubules, so these monocilia are

**FIGURE 15-14** EMT in the primitive streak. Formation of nascent mesoderm during gastrulation is a result of an EMT and tissue migration. Epithelial cells of the epiblast sheet converge toward the primitive streak, where increasing concentrations of signaling molecules, such as WNT3, fibroblast growth factor 8 (FGF8) and nodal, influence cell behavior. Cells in the primitive streak detach from the basement membrane, lose their characteristic apical–basal cell polarity, and undergo rapid and drastic cytoskeletal rearrangements that enable them to delaminate and migrate. A signaling cascade that involves FGF8 and the zinc-finger transcription factor snail causes the downregulation of the epithelial cell-adhesion molecule E-cadherin from adherens junctions, allowing mesodermal cells to migrate away from the streak. Additional activities of the transcription factors eomesodermin (EOMES), mesoderm posterior 1 (MESP1), and MESP2 are required for CDH1 downregulation and EMT, respectively. Nascent mesoderm cells migrate laterally and anteriorly between the epiblast and the overlying VE. In lower vertebrates, chemoattractant–receptor interactions, such as stromal-derived factor 1 (SDF1)–C-X-C-chemokine receptor 4 (CXCR4), cytoskeletal rearrangements regulated by RhoGTPases, or convergence–extension movements that are governed by the Wnt or planar cell polarity pathway, orchestrate these complex cell movements. AVE, anterior VE. (Arnold, S. J.; Robertson, E. J. *Making A Commitment: Cell Lineage Allocation and Axis Patterning in the Early Mouse Embryo*. Nat. Rev. Mol. Cell Biol. 2009, 10 (2), 91–103.)

referred to as “9+0 motile cilia.” In contrast, cells at the periphery of the node have non-motile sensory cilia that lack dynein arms. The motile cilia rotate in a vortical fashion to create a leftward flow of extracellular fluid across the node. This is the so-called “nodal flow model” of left–right determination (Figure 15-16). It has been postulated that this nodal flow carries nodal vesicular parcels (NVPs), which are vesicles that contain morphogens including sonic hedgehog protein (Shh) and RA, across to the left side of the node. This flow of morphogens is detected by the non-motile sensory cilia and leads to a rise in intracellular calcium in the cells on the left side of the node. The secretion of NVPs, release of Shh and RA, and calcium influx into the left-sided cells, are all mediated by signaling through the Fgf pathway. The genes that were expressed only on the left side of the node are also expressed in the left lateral plate mesoderm, resulting in asymmetric gene expression (and hence left–right asymmetry) in the lateral plate mesoderm (18,40,41).

However, using electron microscopy and by studying (i) the expression of the Goosecoid (*Gsc*), which is a gene thought to be responsible for the “organizer” activity

of the node and hence the development of the body axes, and (ii) the expression of *Nodal*, which is closely associated with the node and is one of the genes that is expressed in the left lateral plate mesoderm, a group of authors found that in the rabbit, cells in Hensen’s node are not ciliated, but a single monocilium was identified on each cell posterior (i.e. caudal) notochordal process, which is anterior (i.e. cranial) to the anatomic primitive node. While expression of *Gsc* was present in Hensen’s node and the cranial part of the primitive streak in early stage embryos, *Gsc* expression in the later stage embryos was confined to the prechordal plate. Similarly, *Nodal* expression in the primitive node was transient and had faded by the time the notochordal plate was being formed. However, *Nodal* expression was subsequently detected on both sides of the posterior notochordal plate, and when the embryo was at the 2–3 somite stage, *Nodal* expression became asymmetric and concentrated in the left lateral plate mesoderm. The authors suggested that the posterior notochord is the site of the cilia-mediated nodal flow for the establishment of left–right asymmetry in mammals. They further suggested that the longitudinal

**FIGURE 15-15** Diagrams of the caudal end of chick embryos during two rounds of somitogenesis. Retinoic acid (blue) and Fgf8 (gray) gradients move caudally as the embryo elongates (axis extension) during somitogenesis. In chick, a somite pair forms every 90 min, which constitutes the length of the clock cycle. Expression of cycling genes (red) extends from caudal to cranial, and when expression of these genes spreads cranially to cross the threshold level of *Fgf8* signaling (called the determination wavefront; diagonal line), somites are established (indicated by expression of *Mesp* genes; purple). (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen’s Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

**FIGURE 15-16** Model showing the transport of NVPs by motile cilia and the stimulation of calcium signaling (blue) at the left side of the node by nonmotile cilia. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen’s Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

body axes are determined through the “organizer activity” of the anatomic primitive node (41).

The dynein arms in the motile monocilia contain the left–right dynein protein, encoded by *DNAH11* (axonemal dynein, heavy chain 11), which is the human homolog of the mouse *Lrd* (left–right dynein), and other dynein proteins encoded by various axonemal dynein genes such as *DNAL1*, *DNAI1*, *DNAI2*, and *DNAH5*. The proper assembly and function of dynein require the medaka kintoun protein encoded by *KTU*, and the coiled-coil domain containing proteins 39 and 40 encoded by *CCDC39* and *CCDC40*. Homozygous or compound heterozygous loss-of-function mutations in any one of these genes result in primary ciliary dyskinesia with or without situs inversus (OMIM phenotypic series# 244400) (40). It should be noted that when the cilia are nonfunctional (e.g. immotile), the fluid flow around the functional left–right node is random and there is random expression of the “left-specific” genes on either side. Hence, not all individuals with mutations in these genes will have situs inversus (42).

In the mouse and some other vertebrate models, the nodal flow results in *Nodal* being asymmetrically expressed in the left lateral plate mesoderm. *Nodal* then induces the expression of *Lefty2* and *Pitx2* in the left lateral plate mesoderm, as well as *Lefty1* in the left floor plate of the neural tube. In these animal models, *Lefty1* constrains the expression of *Nodal* to a limited area, while *Lefty2* prevents the spread of the *Nodal* signal from left to right; *Pitx2* is involved in the maintenance of left–right asymmetry during organogenesis. Heterozygous loss-of-function mutations in *NODAL* have been found to cause heterotaxy (situs ambiguus), which is a clinically and genetically heterogeneous group of conditions characterized by abnormal left–right placement of thoracic and/or abdominal organs and is often associated with congenital heart malformations and asplenia (in the case of *NODAL* mutations) or polysplenia (OMIM# 270100) (43). Mutations in many other genes have been associated with heterotaxy including *ZIC3* (OMIM# 306955), an X-linked gene that encodes a protein hypothesized to act upstream of *NODAL*, *CFC1* (OMIM# 605376, 613853), which encodes a co-receptor for *NODAL*, and *LEFTY2* (OMIM# 601877). However, mutations in *LEFTY1* have not been reported to be associated with any heterotaxy or situs inversus syndromes, while mutations in *PITX2* (OMIM# 601542) have only been reported to cause syndromes associated with ocular anomalies but without heterotaxy or situs inversus such as Axenfeld–Rieger syndrome, iridogoniodygenesis, Peters anomaly, and ring dermoid of cornea. This suggests that caution should be exercised in extrapolating animal experimental data to humans.

**15.6.6.1 Spatial Context and Functional Redundancy of Developmental Genes.** Many genes that are expressed in early embryonic development are also involved in other developmental processes at the later stages in embryonic and fetal development. Moreover,

there is some functional redundancy among some of these genes such that mutations in one or more of these genes may not lead to embryonic lethality. For example, although *SOX2* is one of the four pluripotent-inducing genes, it is also involved in the maintenance of neural stem cells and hence neurogenesis, development of the optic cup by maintaining the neurogenic fate of the retinal neuroepithelium, generation of peripheral sensory and autonomic neurons through interactions with the Notch signaling pathway, and at least in mouse neural stem cells, regulation of *Jag1*, *Gli3*, and *Mycn* through interactions with the *Chd7* cofactor (44–47). Individuals with heterozygous loss-of-function *SOX2* mutations survive to adulthood and have syndromic microphthalmia type 3 (sometimes known as anophthalmia–esophageal–genital syndrome) (OMIM# 206900), which is associated with structural brain malformations, renal and genitalia malformations, and tracheoesophageal fistula or esophageal atresia; the ocular manifestations vary from bilateral microphthalmia or anophthalmia to anterior segment dysgenesis, coloboma, or even a complete lack of ocular phenotype (48). In view of the recently identified interactions between *Sox2* and *Chd7* as discussed above, it is not surprising that these phenotypic features overlap with those seen in CHARGE syndrome (OMIM# 214800) caused by heterozygous mutations in *CHD7*.

Another pluripotent-inducing gene involved in early embryonic development is *SALL4*. Heterozygous loss-of-function mutations in *SALL4* result in either Duane–radial ray syndrome (also known as Okihiro syndrome) (OMIM# 607323) or IVIC syndrome (OMIM# 147750); IVIC is the abbreviation for Instituto Venezolano de Investigaciones Científicas in Caracas, Venezuela, where the first family with this syndrome was reported (49). Duane–radial ray syndrome is characterized by Duane anomaly, radial ray malformations that may include hypoplasia/aplasia of the thumbs and radii or preaxial polydactyly, and sensorineural hearing loss; the allelic acro–renal–ocular syndrome is also associated with structural renal malformations. Duane anomaly is the absence of the abducens nerve (cranial nerve (CN) VI) and aberrant innervation of the lateral rectus muscle by the oculomotor nerve (CN III) leading to limited abduction or adduction of the eye, associated with retraction of the globe and narrowing of the palpebral fissure on adduction (50). IVIC syndrome is another allelic disorder that can present with imperforate anus, mild thrombocytopenia and mild leukocytosis, in addition to the other clinical findings described above (49). Recently, it was shown that *Sall1* upregulates the expression of *Nanog* in mouse embryonic stem cells and interacts physically with both *Nanog* and *Sox2*, and it also suppresses the differentiation of ectoderm and mesoderm. These data suggest that *Sall1* is directly involved in the regulation of pluripotency and tissue differentiation in early embryonic development (51). Heterozygous mutations in *SALL1* result in Townes–Brocks syndrome (OMIM# 107480),

characterized by imperforate anus, dysplastic ears with associated sensorineural or conductive hearing loss, and thumb malformations (typically preaxial polydactyly, triphalangeal or hypoplastic thumbs); renal anomalies are also commonly associated with this syndrome (52). It was thought that Townes–Brocks syndrome was caused by dominant negative mutations in *SALL1*, but with the identification of *SALL1* deletions in patients with very similar phenotypes, it is now believed that haploinsufficiency of *SALL1* may result in the same condition (53). Thus, it is clear that mutations in at least two *Sall* family genes, *SALL1* and *SALL4*, are completely compatible with life despite their roles in early embryonic development, and both genes are involved in the development of a number of different organ systems beyond the early embryonic period. It is also notable that both Duane–radial ray syndrome and IVIC syndrome have phenotypic features that closely resemble those seen in Townes–Brocks syndrome, which suggests that these two genes may be involved in the regulation of similar, but not necessarily identical, developmental pathways in the same organ systems, consistent with the finding that *Sall1* and *Sall4* share structural and functional similarities (51).

As blastocysts mature and become “attachment competent” for implantation, one of the heparan sulfate proteoglycans that they express on their surfaces is HSPG2 (basement membrane-specific heparan sulfate proteoglycan core protein; also known as perlecan). However, homozygous or compound heterozygous hypomorphic mutations in HSPG2 do not result in failure of implantation, presumably because there is functional redundancy with other heparan sulfate proteoglycans. Instead, these mutations result in Schwartz–Jampel syndrome type 1 (OMIM# 255800) or the more severe Silverman–Handmaker type of dyssegmental dysplasia (DDSH) (OMIM# 224410). Schwartz–Jampel syndrome is characterized

by myotonia with sustained skeletal muscle contractions on electromyography, joint stiffness, and chondrodysplasia with short stature, kyphoscoliosis, and bowing of the long bones; DDSH is a neonatal lethal form of short-limbed dwarfism with anisodondyly (i.e. variations in size and shape of vertebral bodies), micromelia, and micrognathia. The functions of HSPG2 include cell adhesion, maintenance of the basement membrane and cartilage, and anchoring of acetylcholinesterase at neuromuscular junctions, failure in which may account for the myotonia (54,55).

## 15.7 REGULATION OF GENE EXPRESSION IN DEVELOPMENT

Almost all somatic cells in the body contain an identical set of genes—the concept of *genomic equivalence*. Therefore, for each cell to differentiate into specialized tissues and organs, differential gene expression must occur. Such regulation of gene expression can occur at different steps in the process from transcription of the genes to posttranslational modifications of the proteins encoded by the genes.

### 15.7.1 Transcriptional Regulation

**15.7.1.1 Regulation by Histone Modification.** Eukaryotic chromosomes are composed of chromatin, a complex of DNA, proteins (primarily histones), and small amounts of RNA. Every 145–147 base pairs of DNA wrap in 1.65–1.67 loops around an octamer of histones comprising two molecules each of histones H2A, H2B, H3, and H4, forming the nucleosome, which is the basic unit of chromatin (Figure 15-17). The nucleosomes are linked to each other by about 60 bp of DNA, attached to which are histone H1. These nucleosomes usually form a compact solenoid structure, held together by histone

**FIGURE 15-17** Model for the arrangement of nucleosomes in the highly compacted solenoidal chromatin structure. Histone “tails” protruding from the nucleosome subunits allow for the attachment of chemical groups. (Gilbert, S. F. *Developmental Biology*, 9th ed., Sinauer Associates, Inc.: Sunderland, MA, 2010.)

H1, that prevents transcription factors and enzymes from binding to the DNA, thereby inhibiting transcription. Extending from each histone in the nucleosome is an amino acid “tail” that can be acetylated or methylated to regulate gene expression (11).

The acetylation of lysine residues on the tails of histones H3 and H4 by histone acetyltransferases results in destabilization of the nucleosomes, activating transcription (Figure 15-18); histone deacetylases stabilize the nucleosome and repress transcription. Methylation of histone tails by histone methyltransferases may result in either activation or repression of transcription, depending on the specific amino acid residue and the acetylation or methylation states of the surrounding amino acids.

Heterozygous loss-of-function mutations in the histone acetyltransferases CREBBP and EP300, both of which interact with each other and acetylate the lysine residue at amino acid position 56 of histone H3 (H3K56), result in Rubinstein-Taybi syndrome types 1 and 2 (OMIM# 180849 and 613684), respectively. Heterozygous loss-of-function mutations in euchromatin histone methyltransferase 1 (EHMT1), which forms part of the E2F-6 transcription repressor complex and methylates H3K9, result in Kleeftstra syndrome (OMIM# 610253). Heterozygous loss-of-function mutations in *MLL2*, which encodes a H3K4 methyltransferase, result in Kabuki syndrome (OMIM# 147920). All of these syndromes are characterized by intellectual disabilities, specific dysmorphic features, and multiple congenital anomalies, perhaps reflecting the ubiquitous role that histone modifiers play in the development of various organ systems. However, mutations in some histone-modifying genes lead to more limited phenotypic manifestations. For example, SIRT6 is a H3K9 and H3K56 histone deacetylase that associates with chromatin at the telomeres and is required for the stable association of the WRN protein with telomeric chromatin, together with which telomere function

and replication is maintained; in human cell cultures, SIRT6 deficiency leads to premature cellular senescence. Since homozygous loss-of-function mutations in *WRN* (also known as *RECQL2*) result in Werner syndrome (OMIM# 277700), an autosomal recessive premature aging syndrome that is not associated with intellectual disability nor with multiple congenital anomalies, it has been hypothesized that mutations in *SIRT6* could lead to a similar premature aging syndrome, although *SIRT6* mutations have not been reported in human patients (56,57).

Differentiated cells in tissues and organs have to retain identical sets of expressed and repressed genes through each mitotic generation. At the chromatin level, this is achieved through the Polycomb group (PcG) proteins that maintain genes in an inactive state and the Trithorax group (TrxG) proteins that keep genes active. PcG proteins function as part of large multi-protein complexes, including different versions of Polycomb Repressive Complexes 1 and 2 (PRC1 and PRC2); the specificity of each version may depend on the subunits within the complexes. PRC2 can di- and trimethylate H3K27 (H3K27me<sub>2/3</sub>) through the histone methyltransferases Ezh1 and Ezh2. PRC1 can monoubiquitylate (also known as monoubiquitinate) the lysine residue at amino acid position 119 of histone H2A (H2AK119ub) through the ubiquitin ligases Ring1A and Ring1B; one component of PRC1 can also bind specifically to H3K27me<sub>2/3</sub>. For some genes, there may also be another set of PcG that binds to the methylated tail of histone H3 to keep the histone in a methylated state. In contrast, some TrxG proteins can reverse the effects of PcG enabling the binding of transcription factors, or maintain H3K4 in an active, trimethylated state (11,58).

**15.7.1.2 Regulation by Cohesin.** Although the cohesin complex is one of the three “structural maintenance of chromosome” (SMC) protein complexes that are responsible for chromosome condensation and segregation during mitosis and meiosis, it is now known that cohesin also

**FIGURE 15-18** The tail of histone H3 sticks out from the nucleosome and is capable of being methylated or acetylated. Here, lysines can be methylated and recognized by particular proteins. Methylated lysine residues at positions 4, 38, and 79 are associated with gene activation, whereas methylated lysines at positions 9 and 27 are associated with repression. The proteins binding these sites are represented above the methyl group. (Gilbert, S. F. *Developmental Biology*, 9th ed., Sinauer Associates, Inc.: Sunderland, MA, 2010.)

regulates gene transcription independent of its SMC functions. Binding of the cohesin complex to chromosomes is dependent on the presence of the Nipped-B-Mau-2 complex (encoded in humans by *NIPBL*) and ATPase of SMC1 and SMC3, both of which are proteins in the cohesin complex. It is thought that mediation of sister chromatid cohesion requires relatively small amounts of cohesin bound to chromosomes while regulation of gene transcription requires larger amounts of cohesin to be bound to chromosomes. Cohesin appears to bind close to the transcription start sites of specific genes that are active, but it also binds to CCCTC-binding factor (CTCF) binding sites, which are sites that block enhancer–promoter interactions and repress transcription. However, with some exceptions, cohesin does not usually bind to genes that have been silenced by PcG through H3K27me3 (*vide supra*). One of the genes that cohesin upregulates is *myc*, a protooncogene which itself encodes a factor that regulates the expression of genes involved in cellular growth and proliferation. Cohesin also downregulates certain genes that promote cellular differentiation (11). Heterozygous mutations in *NIPBL* result in Cornelia de Lange syndrome type 1 (OMIM# 122470), hemizygous mutations in X-linked *SMC1A* result in Cornelia de Lange syndrome type 2 (OMIM# 300590), and heterozygous mutations in *SMC3* result in Cornelia de Lange syndrome type 3 (OMIM# 610759). All three types of Cornelia de Lange syndrome are characterized by intellectual disability and distinctive facial features; in addition, individuals with *NIPBL* mutations usually have hypertrichosis, micro-melia or other upper limb skeletal defects, and in some instances, multiple congenital anomalies.

**15.7.1.3 Regulation via DNA Sequences: Promoters, Enhancers, Silencers, and Insulators.** Starting from the most upstream (5') end, the DNA sequence of a protein-coding gene comprises in order, the promoter region, the transcription initiation site (also known as the cap sequence), the 5' untranslated region (5' UTR) (also known as the leader sequence), the translation initiation site (ATG), exons and introns, a translation termination codon, the 3' untranslated region (3' UTR), and the transcription termination sequence (Figure 15-19) (11).

In mammals, the core promoter region overlaps with exon 1 of the gene and contains one or more core promoter

elements such as the “TATA box” (i.e., containing the consensus nucleotide sequence TATAWAAR) [*per International Union of Pure and Applied Chemistry (IUPAC) nomenclature*: W=nucleotide A or T; R=nucleotide A or G] typically about 30–31bp upstream of the transcription initiation site, the initiator element (Inr) with the consensus sequence YYANWYY [*IUPAC nomenclature*—Y=nucleotide C or T; N=any nucleotide] about 2bp upstream to 5bp downstream of the transcription initiation site and the A nucleotide being designated as the +1 nucleotide regardless of whether transcription is predominantly initiated at this nucleotide, and downstream core elements (three subunits that lie 6–34bp downstream of the transcription initiation site). Some TATA boxes in core promoters are flanked by an upstream TFIIB (transcription factor II B) recognition element (BREu) with the consensus sequence SSRGCGC and a downstream TFIIB recognition element (BREd) with the consensus sequence RTDKKKK [*IUPAC nomenclature*: S=nucleotide G or C; D=nucleotide A, G, or T; K=nucleotide G or T]. There are two classes of core promoters—those that regulate one or a small cluster of transcription initiation sites (the “focused core promoter”) and those that regulate a broad range of potential transcription initiation sites over a 50–100bp region (the “dispersed core promoter”), with the TATA box being more common among the focused core promoters (59). In addition, there are proximal promoter elements (also known as upstream promoter region) in the DNA sequence that are thought to promote interactions between the enhancers and the core promoter region (60). Within the 3' UTR is the “polyA addition site” where polyadenylation of the RNA transcript occurs, that is, the addition of a long stretch of adenine nucleotides to the RNA transcript. Polyadenylation helps to stabilize the RNA, enables the RNA to enter the cytoplasm, and allows the resultant mRNA in the cytoplasm to be translated. On the same chromosome are DNA sequences, known as enhancers, that bind transcription factors and regulate the efficiency of transcription from a given promoter. Due to the compact structure of the chromatin (*vide supra*), these enhancers may regulate the expression of genes thousands of base pairs away, but always on the same chromosome (hence classified as *cis*-regulatory elements); moreover, enhancers may lie upstream (5'), downstream (3'), or within the introns

**FIGURE 15-19** Schematic representation of the locations of the core promoter elements, 5' untranslated region (leader sequence), exons, introns, and 3' untranslated region. (Gilbert, S. F. *Developmental Biology*, 9th ed., Sinauer Associates, Inc.: Sunderland, MA, 2010.)

of the genes that they regulate. Each enhancer may bind several different transcription factors, and it is the specific enhancer-transcription factors combination that determines whether the promoter of a given gene is activated. A gene can have multiple enhancers, each of which can bind to different, and sometimes multiple, transcription factors. For example, *PAX6* has a specific enhancer for each of the cell type or tissue in which it is expressed (retina, lens/cornea, neural tube, and pancreas) and each enhancer binds to a specific set of transcription factors, regulating the expression of *PAX6* in the different tissues. Moreover, each transcription factor may bind to the enhancers and promoters of different genes. The requirement for a specific set of transcription factors to bind to an enhancer before a given gene is activated enables coordinated gene expression in a developing tissue or organ. For example, many genes involved in the development of the lens contain an enhancer that promotes gene expression only when *PAX6*, in addition to other transcription factors, is bound to it, so none of these genes will be activated until *PAX6* is present (11). Mutations in enhancers can lead to syndromes associated with dysfunction of the genes that they regulate in specific tissues or organs. For example, expression of the sonic hedgehog gene (*SHH*) in the developing limb bud is regulated by the ZRS (ZPA (zone of polarizing activity) Regulatory Sequence), which lies within intron 5 of *LMBR1*, about 1 Mb away from *SHH* on chromosome 7q36.3; gain-of-function mutations in ZRS result in preaxial polydactyly type II, triphalangeal thumb-polysyndactyly syndrome, and isolated triphalangeal thumbs (OMIM# 174500) (61–63), whereas complete loss-of-function mutations in ZRS appear to result in acheiropody (OMIM# 200500), which is characterized by congenital “amputations” of all four limbs and aplasia of hands and feet (64). Of note, none of these syndromes are associated with the brain or ocular malformations typically seen in germ line *SHH* mutations, which could be due to the tissue specificity of this enhancer. *LMBR1* itself is thought to encode a transmembrane receptor and does not appear to be involved in limb development, but it is most strongly expressed in the heart and the pancreas instead (65).

Once a set of transcription factors has bound to an enhancer, a histone-modifying enzyme such as a histone acetyltransferase or histone methyltransferase may be recruited by the transcription factors to activate transcription. In addition to their roles in “dissociating” or activating the nucleosomes, transcription factors can also stabilize the transcription preinitiation complex, thereby allowing RNA polymerase in the complex to bind to the core promoter region to initiate transcription (11). Transcription factors may be categorized into different families based on their molecular structures, as shown in Table 15-3.

Mutations in genes encoding transcription factors can lead to human developmental disorders. For example, MITF is a transcription factor that activates the promoter of the tyrosinase (*TYR*) gene, which in turn

catalyzes the conversion of tyrosine to melanin in pigment production. MITF also activates the promoter of *GPR143* (previously known as *OA1*), a gene that encodes a G protein-coupled receptor expressed only in melanocytes and retinal pigment epithelium. Heterozygous mutations in *MITF* result in Waardenburg syndrome type 2A (OMIM# 193510), characterized by a white forelock, leukoderma, and sensorineural hearing loss at birth (melanocytes in the cochlea may affect the function of inner ear hair cells), as well as an allelic condition, Tietz syndrome (OMIM# 103500), characterized by congenital sensorineural hearing loss, white-blond hair, and light-colored skin.

Silencers are DNA elements (sequences) that repress gene transcription. There are two main classes of silencers—silencer elements that interfere with the formation of the transcription preinitiation complex via transcription factors that repress transcription, and negative regulatory elements that prevent the binding of transcription factors to their *cis*-regulatory DNA sequences. Silencer elements are located upstream of the genes that they regulate, while negative regulatory elements may

**TABLE 15-3** Some Major Transcription Factor Families and Subfamilies

Family	Representative Transcription Factors	Some Functions
Homeodomain		
Hox	Hoxa1, Hoxb2, etc.	Axis formation
POU	Pit2, Unc-86, Oct-2	Pituitary development; neural fate
LIM	Lim1, Forkhead	Head development
Pax	Pax1, 2, 3, 6, etc.	Neural specification; eye development
Basic helix-loop-helix (bHLH)	MyoD, MITF, daughterless	Muscle and nerve specification; <i>Drosophila</i> sex determination; pigmentation
Basic leucine zipper (bZip)	C/EBP, AP1	Liver differentiation; fat cell specification
Zinc finger		
Standard	WT1, Krüppel, Engrailed	Kidney, gonad, and macrophage development;
Nuclear hormone receptors	Glucocorticoid receptor, estrogen receptor, testosterone receptor, retinoic acid receptors	Secondary sex determination; craniofacial development; limb development
Sry-Sox	Sry, SoxD, Sox2	Bend DNA; mammalian primary sex determination; ectoderm differentiation

Reproduced from Reference (11).

be located upstream, downstream, or within introns or exons of the genes that they regulate (60). Some silencers restrict the expression of genes to highly specific tissues, such as the neural restrictive silencer element found in certain genes that prevent the activation of the promoters of those genes in tissues other than neurons (11).

Insulators are *cis*-regulatory DNA sequences that prevent the interactions between enhancers or silencers and one or more of the genes that they regulate. Enhancer-blocking insulators, which often contain binding sites for the CTCF, prevent enhancer–promoter interactions, thereby preventing gene expression. Barrier insulators lie between heterochromatin and euchromatin domains, and serve to prevent chromatin-mediated gene silencing (60).

**15.7.1.4 Regulation by DNA Methylation and Demethylation.** Histone modifications, as described above, confer short-term “epigenetic memory” to the cells in that those modifications can be altered before or during mitosis. Long-term, stable and heritable epigenetic regulation is usually achieved through methylation of DNA itself at CpG sites (i.e. a cytosine–guanine doublet linked by a phosphodiester bond as in a strand of DNA) by converting cytosine to 5-methylcytosine, although methylation also occurs at non-CpG sites in embryonic stem cells. The patterns of DNA methylation across the genome are first established in the blastocyst stage by the *de novo* DNA methyltransferases, DNMT3A and DNMT3B. This is subsequently maintained during DNA replication by the maintenance or perpetuating DNA methyltransferase, DNMT1, which recognizes the methylcytosine residue one strand (a hemimethylated CpG site) and methylates the cytosine residue in the CpG site on the complementary strand, although it can also methylate CpG sites. Lack of DNMT1 results in absence of methylation on the daughter strands, leading to loss of DNA methylation after multiple rounds of cell division. Methylated cytosines in the promoter regions repress transcription from specific genes, either by preventing the binding of transcription factors to enhancers or facilitating the binding of specific proteins that then methylate or deacetylate histones. For example, when MeCP2 is bound to the methyl group in methylated cytosine, it recruits histone deacetylases and histone methyltransferases leading to the stabilization of the nucleosomes and preventing gene transcription (11,66,67). Homozygous or compound heterozygous mutations in DNMT3B, typically in the methyltransferase domain, result in immunodeficiency–centromeric instability–facial anomalies (ICF) syndrome type 1 (OMIM# 242860). The immunodeficiency is characterized by variably low IgA, IgG, and IgM, and in some patients, low T cells, but B cells are usually present. The centromeric instability is manifested as chromosomal rearrangements (such as deletions of whole chromosome arms and multibranched (multi-radial) chromosomes) in the heterochromatic regions adjacent to the centromeres of chromosome 1, 16, and less frequently, chromosome

9, in phytohemagglutinin-stimulated lymphocytes; these regions are hypomethylated, at least in these specific chromosomes, consistent with the deficiency in DNMT3B. It has been hypothesized that hypomethylation of the heterochromatin in those pericentromeric regions affect the expression of genes elsewhere in the genome. Other manifestations of ICF syndrome type 1 include facial dysmorphism and variable degrees of developmental delays or intellectual disability (68). Recently, heterozygous mutations in *DNMT1* have been shown to cause hereditary sensory neuropathy type 1E (also known as hereditary sensory neuropathy with dementia and hearing loss) (OMIM# 614116), manifested as sensory ataxia, early-onset dementia before 50 years old, sensorineural hearing loss in the 20s and 30s, and death by early mid-50s in most patients. These mutations impair the folding of DNMT1 and hence its enzymatic activity, leading to global hypomethylation but local hypermethylation at CpG sites of specific promoters (69).

## 15.7.2 Posttranscriptional Regulation: Before Translation of mRNA

**15.7.2.1 RNA Editing.** In some cells, after the pre-mRNA (also known as the primary transcript) has been transcribed from DNA, it undergoes RNA editing, which in humans involves the substitution of bases that have been transcribed, specifically amination of uridine to cytidine (U-to-C), deamination of cytosine to uracil (C-to-U), or deamination of adenosine to inosine (A-to-I). Such editing of pre-mRNA can result in alterations of the splice donor/acceptor sites, regulatory sequences, and start/stop codons, thereby contributing to the variety of different proteins that a single gene can encode for. The carboxyl-terminal domain of RNA polymerase II is involved in coordinating pre-mRNA editing and splicing to ensure that RNA editing, which requires the presence of specific introns, occurs before splicing (70).

The commonest form of RNA editing in humans, A-to-I conversion, is mediated by the ADARs (adenosine deaminases that act on RNA) family of enzymes, which bind to double-stranded RNA formed by a duplex comprising an exon and an intron downstream of the exon. If this conversion occurs in the coding region of the transcript, the inosine base will be read as guanosine during translation; if this conversion occurs around a splice site, it could lead to the gain or loss of that splice site. Heterozygous mutations in *ADAR1*, a ubiquitously expressed member of ADARs, result in dyschromatosis symmetrica hereditaria (DSH) (OMIM# 127400), characterized by hyperpigmented and hypopigmented macules on the dorsum of the hands and feet, and to a lesser extent, on the face that first appear in infancy or early childhood; the affected patients are otherwise healthy. The exact pathogenesis of DSH and the reason for the specific distribution of the lesions are unknown. Another member of the ADARs family, *ADAR2*, converts glutamine to arginine

at amino acid position 607 in the primary transcript of *GRIA2*, which encodes the beta subunit of the glutamate receptor in the central nervous system. Although *ADAR2* is expressed in multiple tissues, its substrate appears to be restricted to a single primary transcript in the central nervous system, and it is partly responsible for neuronal calcium homeostasis through proper assembly of the glutamate receptors. Mutations in *ADAR2* have not been reported in humans, perhaps because such mutations would lead to neuronal death and not be compatible with life, although homozygous null *Adar2* mice live to the postnatal day 20, albeit with seizures. Primary transcripts from a number of other neurotransmitter receptors in the central nervous system are also edited by various members of the ADARs family (70,71).

The apolipoprotein B mRNA editing enzyme, catalytic polypeptide 1 (APOBEC1) mediates the C-to-U deamination in the pre-mRNA of *APOB* in intestinal cells, resulting in the conversion of a codon for glutamine into a stop codon. The unedited *APOB* transcript encodes ApoB-100, which is synthesized in the liver and forms part of very low-density lipoproteins, while the edited transcript encodes ApoB-48, which is synthesized in the small intestines and forms part of chylomicrons and chylomicron remnants (71).

**15.7.2.2 Alternative Splicing.** The introns and in some cases, selected exons, from pre-mRNA are spliced out by spliceosomes to form mature mRNA, typically before the mRNA is exported from the nucleus to the cytoplasm. Different exons from the same pre-mRNA may be spliced out in different cells or tissues or at different developmental stages, a phenomenon known as alternative splicing, which contributes to the diversity of proteins that can be encoded by a single gene; the different proteins that arise from alternative splicing are known as splicing isoforms. Sometimes, different splicing isoforms can have very different functions. For example, depending on how an alternative 5' splice site in the first coding exon of *BCL2L1* (also known as *BCLX*) is used, either a large isoform, BCLXL, that inhibits apoptosis or a smaller (shorter) isoform without exon 2, BCLXS, that promotes apoptosis will be produced. It has been estimated that more than 90% of human protein-coding genes undergo alternative splicing (11).

The spliceosome is made up of small nuclear RNAs (snRNAs) including the small ribonucleoproteins (snRNPs) U1, U2, U4, U5, and U6, as well as proteins known as splicing factors. The U1 snRNP recognizes and binds to the consensus sequence at the 5' splice site (i.e. start of intron) while the U2 snRNP binds to a "branch point" sequence within the intron close to the 3' splice site; the binding of U2 is facilitated by the binding of the U2 auxiliary factor (U2AF) to the polypyrimidine tract close to the branch point sequence. The triple snRNP complex with U4, U5, and U6, then interacts with U1 and U2, and through two sequential transesterification reactions, the intron is cleaved and the two exons are ligated.

The different splicing factors in a spliceosome recognize different sequences as introns; hence, a sequence recognized as an intron in one cell type may be recognized as an exon in another cell type, which forms the basis of alternative splicing. DNA sequences known as splicing enhancers and silencers both in exons and introns close to the 5' and 3' splice sites bind to various splicing factors including the "serine- and arginine-rich" protein family (SR proteins) and the heterogeneous nuclear ribonucleoproteins (hnRNPs). These splicing enhancers and silencers, along with the splice site and branch point sequences, help to identify a specific DNA sequence as an exon versus an intron. Binding of the splicing factors to the splicing enhancers increases the use of those splice sites, while binding to the splicing silencers decreases the use of those sites. Small nucleolar RNAs (snoRNAs) can also regulate the use of specific splice sites (72,73). For example, in the processing of the serotonin receptor 2C gene (*HTR2C*) mRNA, the snoRNA SNORD115 (HBII-52) binds to and promotes the inclusion of exon 5b, which is crucial for the function of the receptor, instead of exon 5a (74). More recently, the mouse ortholog of HBII-52 has also been found to regulate splicing of other genes, including *TAF1* (associated with X-linked dystonia-parkinsonism (OMIM# 314250)) and *CRHR1* (corticotropin-releasing hormone receptor 1) (74). However, human diseases secondary to SNORD115 deficiency have not been reported.

The survival motor neuron (SMN) protein, encoded by *SMN1*, forms a complex with spliceosomal snRNP and Gem-associated protein 2 (encoded by *GEMIN2*, previously known as *SIP1* (survival of motor neuron protein-interacting protein 1)). SMN is critical for the assembly and nuclear import of spliceosomal snRNP and hence pre-mRNA splicing. Mutations in *SMN1* result in spinal muscular atrophy (SMA), and characterized by hypotonia and muscle weakness. It has been suggested that SMA may be partly due to the inability of motor neurons to splice and process specific pre-mRNAs, although it may also be due to disruptions in other roles that SMN may play in the survival of motor neurons such as transportation of substances down the axons. *SMN2* is an ancestral inverted duplication of *SMN1* that lies centromeric to *SMN1*. Each individual has between 0 and 5 copies of *SMN2*. One of the key differences in the sequences between *SMN1* and *SMN2* is a silent cytosine-to-thymine transition in exon 7 of *SMN2* that results in the conversion of an exonic splicing enhancer to an exonic splicing silencer, thereby producing a shorter, unstable SMN protein that lacks exon 7 but is still partially functional. About 85% of the mRNA from *SMN2* is thought to lack exon 7 (73,75). The severity of the SMA phenotype depends on the number of copies of *SMN2*—most children with SMA type 1 (Werdnig-Hoffmann disease) (OMIM# 253300), which is the most severe form and usually lethal by age 2 years, have one or two copies of *SMN2*; in contrast, most children with

SMA type 3 (juvenile SMA or Kugelberg–Wielander disease) (OMIM# 253400) have three or four copies of *SMN2*, manifest weakness after 18 months of age and have a normal life span (76).

The U12-dependent spliceosome is a minor spliceosome that recognizes the 5' splice site with the sequence (G/A)TATCCT and a specific branch site in a relatively small number of genes. In contrast to the more common U2-dependent spliceosome described above, the U12-dependent spliceosome comprises the U11, U12, U4atac, U5, and U6atac snRNPs subunits (the U5 snRNP being common to both the U2 and the U12-dependent spliceosomes). Recently, it was found that homozygous or compound heterozygous mutations in *RNU4ATAC*, which encodes U4atac, result in microcephalic osteodysplastic primordial dwarfism type 1 (MOPD1) (also known as Taybi–Linder syndrome) (OMIM# 210710). The key clinical features of MOPD1 include severe intrauterine growth retardation, microcephaly with structural brain malformations, intellectual disability, and skeletal dysplasia. Of note, *RNU4ATAC* lies within intron 2 of *CLASP1*, which encodes a microtubule-associated protein that regulates microtubule dynamics and stabilizes the mitotic spindle during cell division. However, mutations in *RNU4ATAC* do not affect splicing or expression of *CLASP1* (77,78).

Heterozygous mutations in some members of the precursor mRNA-processing (splicing) factor family including *PRPF3*, *PRPF6*, *PRPF8*, and *PRPF31* result in non-syndromic retinitis pigmentosa, not typically associated with other clinical manifestations.

Myotonic dystrophy type 1 (OMIM# 160900), characterized by muscle weakness, myotonia, cataracts, cardiac conduction defects, and diabetes mellitus in some patients, is caused by expansion of the CTG trinucleotide repeats in the 3' UTR of *DMPK*. The transcribed long CUG repeats in the mRNA have a high binding affinity for the splicing factor MBNL1 (muscleblind-like protein 1), leading to a depletion of this splicing factor and effectively a loss of its activity in the nucleoplasm. At the same time, the abnormally long CUG repeats also lead to upregulation of *CELF1*, which encodes CUGBP Elav-like family member 1 (previously known as CUG-binding protein). CELF-1 regulates the alternative splicing of *CLCN1* (which encodes a chloride channel in skeletal muscle), *TNNT2* (human cardiac troponin T), and *INSR* (insulin receptor), among other genes. It is believed that the phenotypic manifestations of myotonic dystrophy type 1 are due to aberrant alternative splicing as a result of the lack of MBNL1 and excess CELF-1 (72). Hence, although the causative mutation in myotonic dystrophy type 1 is in *DMPK*, it may be the disruption in alternative splicing due to an imbalance in those two splicing factors that underlie the pathogenesis and pleiotropy in this condition. Myotonic dystrophy type 2 (OMIM# 602668), due to an expansion of the CCTG nucleotide repeats in intron 1 of *CNBP* (previously known as *ZNF9*), has

similar but possibly milder manifestations compared to myotonic dystrophy type 1; its pathogenesis is due to the sequestration of MBNL1, which also has a high affinity for the long CCTG repeats.

It should be noted that abnormal splicing of genes does not always result in an undesirable phenotype. Myostatin, encoded by *MSTN*, is a negative regulator of skeletal muscle growth. A child with muscle hypertrophy and unusual strength, but no other clinical manifestations up to age 4½ years (OMIM# 614160), was found to have a homozygous splice donor (5') site mutation that resulted in an aberrantly spliced mRNA with a premature termination codon and hence a lack of myostatin. His mother, who was described as “muscular” and was a former professional athlete, was a heterozygous carrier for this mutation (79).

### 15.7.3 Translational Regulation

The regulation of protein synthesis (i.e. translation of mRNA) in eukaryotes typically occurs during the initiation stage rather than the subsequent elongation and chain termination stages. Translation begins with the assembly of the 43S preinitiation complex comprising the 40S ribosomal subunit and a set of eukaryotic initiation factors (eIFs) including eIF3, eIF1, eIF1A, and the eIF2-GTP-Met-tRNA<sup>Met</sup><sub>i</sub> (eIF2-TC) complex [Met = methionine]. The 43S complex attaches to and scans the mRNA from the 5' UTR until it locates the translation initiation codon, which is usually the first AUG within the consensus sequence GCC(A/G)CCAUGG and is recognized by the anticodon of eIF2-TC. eIF1 and eIF1A facilitate this process by unwinding the secondary structures in the 5' UTR. eIF1 also helps to ensure that eIF2-TC binds only to AUG within the consensus sequence, thereby ensuring that the 43S complex binds to a translation initiation site. The binding of the 43S complex to the translation initiation codon leads to the formation of the 48S initiation complex and the subsequent hydrolysis of eIF2 from GTP resulting in the release of both eIF2-GDP and inorganic phosphate (GTP → GDP + P<sub>i</sub>). The 60S ribosomal subunit then combines with the 48S complex to form the 80S initiation complex. The remaining eIFs then dissociate from the 80S subunit and chain elongation begins. Termination of translation leads to the recycling of the ribosomal subunits that will be used in the next round of translation. The recycling of eIF2-GDP (which will form part of the eIF2-TC complex) is mediated by eIF2B, which functions as a “guanosine nucleotide exchange factor that promotes GDP-GTP exchange” (80). Homozygous or compound heterozygous mutations in the genes that encode any one of the five eIF2B subunits (*EIF2B1*, *EIF2B2*, *EIF2B3*, *EIF2B4*, *EIF2B5*) result in leukoencephalopathy with vanishing white matter (VWM) (OMIM# 603896); mutations in *EIF2B2*, *EIF2B4*, and *EIF2B5* also result in ovarioleukodystrophy, which is the same condition with ovarian failure as

an additional manifestation. These mutations reduce, but almost never completely eliminate, the activity of EIF2B. VWM is characterized by the widespread disappearance of white matter and replacement by cerebrospinal fluid in the central nervous system, resulting in progressive ataxia and spasticity. Other clinical manifestations depend on the type of VWM, as classified by the age of onset. For example, the antenatal form can be associated with congenital hypotonia, seizures, and multiple congenital anomalies including cataracts, renal hypoplasia, and hepatosplenomegaly. The early childhood-onset form is characterized by onset of ataxia between the ages of 1 and 5 years, followed by progressive spasticity with hyperreflexia, tremor, dysarthria, seizures, and optic atrophy. The adult-onset form can present with behavioral issues, cognitive decline, and ovarian dysgenesis in the females. In most postnatal forms of VWM, episodic neurologic deterioration may occur with stresses such as minor head trauma and minor infections (81). VWM appears to selectively affect oligodendrocytes and astrocytes. It has been suggested that these cells are hyperre-active to physiological stress in VWM, possibly due to activation of the “unfolded protein response,” a pathway that is typically activated when there is accumulation of unfolded or denatured proteins in the endoplasmic reticulum (ER). However, the precise pathophysiology of VWM remains unclear (82).

### 15.7.4 Posttranslational Regulation

As the primary polypeptide chain elongates during translation, it is translocated into the lumen of the ER through the binding of the ribosome-primary polypeptide-signal recognition particle (SRP) to the SRP receptor on the ER membrane. Once it enters the lumen of the ER, the primary polypeptide chain begins to fold into its secondary and tertiary structures while translation is still occurring. Within the ER lumen are enzymes that catalyze the posttranslational modifications of the protein. As such, protein folding can influence posttranslational modifications, and vice versa. Once translation is completed and the entire primary polypeptide chain has translocated into the ER, protein folding will be completed and the tertiary protein structure will be assembled into its final quaternary structure, during which further posttranslational modification may occur (83). Posttranslational modification regulates the properties and hence, functions, of a protein by “the addition of a modifying chemical group or another protein to one or more of its amino acid residues” (84). A given protein or amino acid residue may be modified by different types of posttranslational modification at different times. The different types of posttranslational modification are discussed in the following sections.

**15.7.4.1 Phosphorylation.** Serine, threonine, and tyrosine residues are phosphorylated and dephosphorylated by protein kinases and phosphatases, respectively. The

phosphoryl group results in a conformational change in the protein and affects the activity of the protein or protein–protein interactions; some protein domains such as SH2 (Src homology domain 2) and PTB (phosphotyrosine-binding domain) will only recognize phosphorylated tyrosine, while others such as forkhead-associated domain will only recognize phosphorylated serine. Many of these phosphorylated proteins are involved in control of cellular growth, mitosis, and response to DNA damage. The use of phosphorylation to amplify signals involved in these processes is common across multiple species.

**15.7.4.2 Ubiquitination (Also Known as Ubiquitylation).** Ubiquitin is a small protein that can be covalently linked to lysine residues of proteins targeted for intracellular degradation by proteasomes. Ubiquitin is first activated by ubiquitin-activating enzyme 1 (UBE1), followed by conjugation to ubiquitin-conjugating enzyme E2, and ligation to lysine residues of specific proteins by ubiquitin protein ligase E3. The target site can be modified by either a single ubiquitin molecule (monoubiquitination), which regulates endocytosis of receptors and repair of DNA damage, or a chain of ubiquitin molecules (polyubiquitination), which is found in proteins targeted for intracellular proteolysis (84).

Mutations in the X-linked ubiquitin-like modifier-activating enzyme 1 (*UBA1*), previously known as ubiquitin-activating enzyme E1 (*UBE1*), result in X-linked infantile spinal muscular dystrophy (OMIM# 301830). Also known as X-linked distal arthrogryposis multiplex congenita, it is characterized by severe congenital hypotonia, areflexia, and contractures due to poor intra-uterine movements, with loss of anterior horn cells in the spinal cord. It has been postulated that amino acid changes in the interaction domain of *UBA1* result in altered interactions between *UBA1* and gigaxonin, which mediate the degradation of microtubule-associated protein 1B (*MAP1B*). This could then lead to accumulation of *MAP1B* and consequent neuronal cell death (85). Mutations in the X-linked ubiquitin-conjugating enzyme E2A (*UBE2A*) lead to a form of X-linked intellectual disability syndrome (OMIM# 300860) with lack of speech, seizures, widely spaced nipples, a small penis, and generalized hypertrichosis. Mutations in the maternally inherited copy of ubiquitin protein ligase E3A (*UBE3A*), a gene that is imprinted in the brain such that only the maternally inherited copy is normally active, result in Angelman syndrome (OMIM# 105830), which is characterized by intellectual disabilities, minimal speech, seizures, and a generally happy personality. The exact pathogenesis of both syndromes caused by mutations in *UBE2A* and *UBE3A* remains unclear, but they share some overlapping phenotypic features and it is possible that it may be related to excess protein accumulation in neurons due to disruptions in ubiquitination.

**15.7.4.3 Sumoylation.** The small ubiquitin-related modifier (SUMO) proteins are structurally similar to

ubiquitin and conjugate to lysine residues of target proteins through a series of reactions catalyzed by an E1-activating enzyme, a specific E2-conjugating enzyme (ubiquitin-conjugating enzyme E2I (UBE2I); also known as UBC9), and a small number of E3 protein ligases. Sumoylation can change the activity of the sumoylated protein, alter the intracellular localization of the protein, or affect protein–protein interactions. There are four SUMO isoforms, encoded by *SUMO1* to *SUMO4* (86). Haploinsufficiency of *SUMO1* was identified in a girl with non-syndromic unilateral cleft lip and palate (OMIM# 613705) (87), but there have been no other reports of *SUMO1* mutations in patients with cleft lip/palate, so the direct association remains controversial and it has been hypothesized that this association may be modified by environmental factors (88,89).

**15.7.4.4 Acetylation.** Acetylation occurs with the transfer of acetyl groups from acetyl coenzyme A (acetyl CoA) to lysine residues by acetyltransferase leading to neutralization of their positive charge. As discussed in Section 15.7.1.1, acetylation can alter gene expression epigenetically. Acetylated lysines are recognized by a specific bromodomain found in some transcription factors and coactivators. These acetylated transcription factors are able to bind more strongly to DNA. Acetylation also alters protein–protein interactions and the stability of proteins. For example, acetylated E2F transcription factor 1 (E2F1) is more stable than the unacetylated form.

**15.7.4.5 Methylation.** In addition to the methylation of histones and DNA as described above, gene expression can also be regulated by methylation of lysine and arginine residues in specific proteins. Methylated lysine residues interact with the chromodomain while methylated arginine residues interact with the “Tudor domain.” A protein may be methylated to different degrees (mono-, di-, or trimethylation). An example of a protein whose activity is regulated by methylation is p53; methylation can either increase or decrease its activity depending on the site and degree of methylation (84).

**15.7.4.6 Hydroxylation.** The proline residue in proteins that are secreted and those that are involved in intracellular oxygen sensing can be hydroxylated by prolyl hydroxylases. EGLN1 is one of the prolyl hydroxylase domain-containing enzymes that hydroxylates the  $\alpha$ -subunit of hypoxia-inducible factor (HIF), a transcription factor, and targets it for proteolysis when oxygen tension is normal. When the cell is hypoxic, hydroxylation of HIF is diminished, leading to accumulation and increased binding of HIF to an enhancer for erythropoietin, and hence a rise in erythropoietin concentration (84,90). Heterozygous loss-of-function mutations in *ELGN1* lead to familial erythrocytosis-3 (OMIM# 609820) in which hemoglobin concentration and hematocrit are increased but erythropoietin is inappropriately normal.

**15.7.4.7 Glycosylation.** The addition of oligosaccharide chains to the surfaces of some secreted and

membrane-bound proteins is required for proper protein folding and localization. There are two main types of glycosylation: (i) N-linked glycosylation in which an oligosaccharide chain is attached to the amide group of an asparagine residue via *N*-acetylglucosamine; and (ii) O-linked glycosylation in which an oligosaccharide chain is attached to the oxygen in the hydroxyl group of serine or threonine, and less often hydroxyproline and hydroxylysine residues. N-linked glycosylation begins in the ER and is completed in the Golgi apparatus. In contrast, O-linked glycosylation occurs primarily in the Golgi apparatus after protein folding and N-linked glycosylation (if applicable) has been completed (83,91).

Defects in N-glycosylation result in a category of disorders known as congenital disorders of glycosylation (CDG), which are divided into two main groups: CDG-I are due to defects in the assembly and attachment of the oligosaccharide chain to the asparagine residue, while CDG-II are due to defects in the processing of the oligosaccharide chain whereby three glucose and one mannose residues are cleaved from the nascent chain, transported to the Golgi apparatus where other sugars are added to the final structure. Many, but not all, types of CDG are associated with neurological complications (e.g. developmental delay, hypotonia, seizures, cerebellar hypoplasia) and involvement of other organ systems particularly the heart (cardiomyopathy), gastrointestinal (GI) tract (protein-losing enteropathy), liver, and eyes (e.g. coloboma, optic nerve hypoplasia, cataracts) (91,92).

Defects in O-glycosylation result in a number of different disorders with varying phenotypic features. Homozygous or compound heterozygous mutations in *B4GALT7* (xylosylprotein beta 1,4-galactosyltransferase, polypeptide 7), which is involved in synthesis of O-xylosylglycans, result in the progeroid form of Ehlers–Danlos syndrome (OMIM# 130070) characterized by wrinkled skin on the face, osteopenia, hypotonia, and developmental delay, in addition to joint laxity and thin, atrophic scars (91). The polypeptide *N*-acetylgalactosaminyltransferase 3, encoded by *GALNT3*, is involved in the synthesis of O-*N*-acetylgalactosaminyl glycans. Homozygous or compound heterozygous mutations in *GALNT3* are a cause of hyperphosphatemic familial tumoral calcinosis (OMIM# 211900), which presents with hyperphosphatemia, ectopic deposition of calcium phosphate crystals in soft tissues around the large joints, as well as vascular calcifications, retinal angioid streaks, and dental anomalies in some patients. Intracellular proteolysis of the FGF23 is normally prevented by glycosylation mediated by *GALNT3*. In the absence of *GALNT3*, FGF23 is cleaved before secretion, resulting in reduction of intact circulating FGF23, which usually inhibits reabsorption of phosphate by the kidneys (93). Defects in the synthesis of O-mannosylglycans may be due to mutations in protein-O-mannosyltransferase 1 (*POMT1*) or protein-O-mannosyltransferase 2 (*POMT2*), both of which catalyze the first step in the synthesis of O-mannosylglycans,

or in protein O-linked-mannose beta-1,2-*N*-acetylglucosaminyltransferase 1 (*POMGNT1*), which catalyzes the second step in the synthesis of O-mannosylglycans. Mutations in all three of these genes result in a group of congenital muscular dystrophies known as muscular dystrophy–dystroglycanopathy due to abnormal glycosylation of alpha-dystroglycan; O-mannosylated alpha-dystroglycan is found in greatest amounts in the brain and muscle, but it may also be found in other tissues. The mildest forms dystroglycanopathies are the limb-girdle muscular dystrophy–dystroglycanopathies (OMIM# 609308, 613158, 613157) associated with mild to moderate intellectual disability and without structural brain abnormalities that are identifiable on brain MRI. At the other end of the spectrum are those muscular dystrophies associated with structural brain and eye abnormalities in the “muscle-eye-brain” group of disorders (OMIM# 236670, 613150, 253280) such as cobblestone lissencephaly, cerebellar hypoplasia, Dandy–Walker malformations, microphthalmia, retinal dysplasia, and optic nerve hypoplasia.

## 15.8 DEVELOPMENTAL GENE PATHWAYS AND FAMILIES

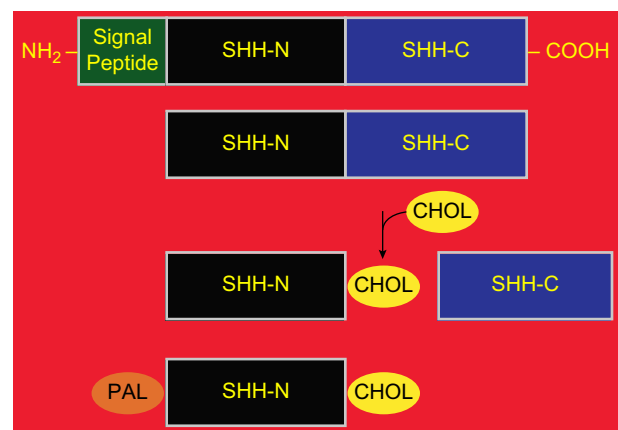

Intercellular signaling through either paracrine or juxtacrine interactions results in the activation of intracellular proteins and factors through a well-defined cascade that eventually initiates or represses the transcription of specific genes. Many of the paracrine factors can be classified into one of four families based on their shared molecular structures, viz. the Hedgehog, Wnt, FGF, and transforming growth factor- $\beta$  families. These factors typically bind to cell surface receptors that comprise three interconnected components: an extracellular ligand-binding domain, a transmembrane region, and a cytoplasmic region with enzymatic domains that remain inactive in the absence of ligand binding; the binding of a paracrine factor to the ligand-binding domain induces a conformational change in the receptor that is transmitted through the transmembrane region to the cytoplasmic region, activating the enzymatic domains of the receptor, thereby catalyzing other intracellular reactions (11). In this section, we will highlight some of the paracrine and juxtacrine signaling pathways that result in a recognizable phenotype in humans when they are perturbed during development.

### 15.8.1 Hedgehog Signaling Pathway

The Hedgehog signaling pathway is involved in the patterning and differentiation of the neural tube, various facial structures including the eyes and the teeth, the limb buds, the heart, and the GI tract. It is therefore critical for the formation of the brain, the distal limbs (fingers and toes), and other organ systems. Inappropriate inactivation of the Hedgehog pathway results in congenital malformations while inappropriate ectopic activation of the

same pathway results in malignancies that may involve the central nervous system, the skin, and skeletal muscles (11,94). There are three Hedgehog paracrine signaling molecules in vertebrates—the Desert Hedgehog (DHH), Indian Hedgehog (IHH), and SHH (Figure 15-20).

Each of the three Hedgehog paracrine signaling ligands (i.e. DHH, IHH, and SHH) is synthesized as a full-length Hedgehog (HH) protein with two components of similar sizes: a “Hedge” domain at the amino-terminal and the “Hog” domain at the carboxyl-terminal. The “Hog” domain has autocatalytic activity and cleaves the full-length Hedgehog protein into the amino-terminal “Hedge” polypeptide (HH-N) and the carboxyl-terminal “Hog” polypeptide (HH-C). This autocleavage reaction requires cholesterol and results in a cholesterol moiety being covalently linked to the carboxyl-terminal end of the HH-N polypeptide. The amino-terminal of HH-N then undergoes palmitoylation, catalyzed by hedgehog acyltransferase (HHAT), resulting in the covalent attachment of an amide-linked palmitate. Thus, HH-N is now “double lipid-modified” (i.e. bilipidated) with palmitate at the amino-terminal and cholesterol at the carboxyl-terminal. HH-N is the active signal-transducing component of HH. The bilipidated HH-N molecule is secreted from the cell in which it was synthesized; HH-C diffuses away. The secretion of HH-N into the extracellular space requires the transmembrane protein, DISP1 (protein dispatched homolog 1), which may be involved in the transportation of HH-N across the plasma membrane and perhaps the processing of HH-N into lipoprotein multimers; it is possible that DISP2 (protein dispatched homolog 2) may also be involved in these processes. Both DISP1

**FIGURE 15-20** SHH has an N-terminal signaling domain [SHH-N] and a C-terminal catalytic domain [SHH-C] that causes autocleavage of the protein, resulting in an ester-linked cholesterol moiety [CHOL] at the carboxy-terminal end of the signaling domain; the catalytic portion diffuses away. Following the addition of the cholesterol adduct, the action of Skinny hedgehog [Ski] acyltransferase adds an amide-linked palmitate [PAL] to the N-terminal end of the signaling domain. In the responding cell, this bilipidated sonic hedgehog [PAL-SHH-CHOL] becomes the ligand for PATCHED 1 [PTCH 1]. (Cohen, M. M., Jr. *Hedgehog Signaling Update*. Am. J. Med. Genet. A 2010, 152A (8), 1875–1914.)

and DISP2 are the human homologs of the *Drosophila* DISP (dispatched) protein. The newly secreted HH-N remains closely associated with the plasma membrane through interactions with glypicans, a form of heparan sulfate proteoglycans. The HH-N is eventually released from the cell surface following cleavage of the glypican anchoring molecule by Notum, and it is transported to the target cells in lipoprotein particles; the transport of HH-N to the target cells is also dependent on the biliarypidation of HH-N. This model is based largely on our understanding of the process in *Drosophila*. Details of the secretion and transport of HH-N in vertebrates are still being elucidated (94,95).

In general, PTC1 (protein patched homolog 1), encoded by *PTCH1*, is the receptor for HH-N on the surface of the target cells, although in some cells, it is thought that SHH-N in particular binds to PTC2 (encoded by *PTCH2*) instead of PTC1. CDON (cell adhesion molecule-related/downregulated by oncogenes) and BOC (Brother of CDON) are co-receptors that facilitate the binding of HH-N to PTC1, and presumably PTC2. Recently, GAS1, a membrane-bound HH-N binding protein, was shown to be an essential HH-N co-receptor for SHH-mediated neural and limb patterning, and the authors hypothesized that CDON, BOC, and GAS1 interact physically with PTC1 (96).

When HH-N is not bound to PTC1, PTC1 inhibits SMO (smoothened), the signal transducer in the HH pathway, which is normally located across the membrane of intracellular vesicles within the target cells, possibly via vitamin D3. Transcription of genes in the HH signaling pathway is mediated by the GLI family proteins (GLI1, GLI2 and GLI3), which are transcription factors that contain a zinc finger domain. GLI1 and GLI2 are transcriptional activators. The full-length GLI3 is a transcriptional activator, but cleavage of its C-terminal results in a repressor form of GLI3. Of note, *GLI1* is a target of the SHH pathway and is transcribed after GLI2 is activated (97). When SMO is inhibited (i.e. when HH-N is not bound to PTC1), GLI3 is phosphorylated by protein kinase A, glycogen synthase kinase 3, and casein kinase 1. The phosphorylated GLI3 associates with SUFU (suppressor of fused homolog) and is recognized by BTRC (beta-transducin repeat-containing protein), leading to the ubiquitination and degradation of the C-terminal portion of GLI3, leaving the N-terminal component that is a transcription repressor. A similar process leads to the degradation of the entire GLI1 and GLI2 proteins (94,98). Some authors have suggested that GLI2 has a similar N-terminal transcription repressor component and can be similarly cleaved to form a repressor too, although the GLI3 repressor is more potent than the GLI2 repressor (97,99). Therefore, genes that are regulated by HH-N are not transcribed in its absence.

When HH-N binds to PTC1 and its co-receptors CDON/BOC, SMO is activated, possibly via oxysterols. Activated SMO translocates from the membrane of the

intracellular vesicles to the axoneme of the primary cilium (typically one nonmotile primary cilium per mammalian cell). Of note, the primary cilium is present only when the cells are not in mitosis; the cilium is reabsorbed just before mitosis and re-assembled after mitosis. The SUFU–GLI complexes accumulate at the tip of the cilium where SMO activity leads to the dissociation of these SUFU–GLI complexes. This, in turn, prevents the degradation of GLI1 and GLI2, and the ubiquitination of full-length GLI3, thereby promoting the transcription of genes regulated by the HH-N pathways. The accumulation of the SUFU–GLI complexes at the tip of the cilium is facilitated by the kinesin protein KIF7, which interacts with the GLI proteins (94,98).

Hedgehog signaling can be modulated by other proteins, including HHIP (Hedgehog-interacting protein), the Ras-associated protein RAB23, and the serine/threonine kinase ULK3. HHIP, which can be either attached to the cell surface or secreted, binds to HH-N and inhibits the Hedgehog signaling pathway (100). RAB23 inhibits GLI2 and promotes the processing (cleavage) of GLI3 into its repressor form, and is hence a negative regulator of the pathway. It is believed that RAB23 acts intracellularly downstream of SMO, although the exact targets have not been clearly identified (101). In contrast, ULK3 binds to the SUFU–GLI2 complex, and it has been hypothesized that in the absence of SHH-N, ULK3 promotes the phosphorylation of full-length GLI2 by protein kinase A, glycogen synthase kinase 3, and casein kinase 1, leading to cleavage of GLI2 into the repressor form. However, in the presence of SHH-N, ULK3 dissociates from the complex and by itself phosphorylates and activates full-length GLI2, thereby promoting the translocation of active GLI2 into the nucleus. Therefore, ULK3 may be both a negative and positive regulator of the pathway, depending on the absence or presence of SHH-N (97).

An overview of the birth defects, congenital syndromes, and malignancies associated with mutations in the various genes in the Hedgehog signaling pathway is provided by Cohen (94). The neurological phenotypes that result from a disruption in the SHH pathway have been reviewed by Murdoch and Copp (99).

Mutations in several genes, including *SHH*, *PTCH1*, *CDON*, *GAS1*, and *GLI2*, that lead to decreased signaling through the SHH pathway can result in the holoprosencephaly spectrum (OMIM# 236100) in humans and in some animal (mainly mouse) models (102). These are usually heterozygous (autosomal dominant) mutations in humans but homozygous (null) mutations in the animal models; heterozygous mutations of these genes in mouse models do not usually result in any observable neurological phenotype. Note that almost all the reported mutations in *PTCH1* that result in holoprosencephaly are missense mutations that either alter the ability of PTC1 to bind to SHH-N or possibly increased signaling through the Hedgehog signaling pathway in the target cells since PTC1 normally inhibits the pathway in

the absence of HH-N. The expressivity of many of these genes is highly variable, ranging from cyclopia with alobar holoprosencephaly at the severe end of the spectrum to hypotelorism or single maxillary incisor alone without any observable brain malformations at the mildest end; the penetrance is also incomplete even within a single family (103,104). Although it has been suggested that mutations affecting the signaling of all HH-N proteins (i.e. receptors and signal transducers in the target cells) tend to result in a more severe phenotype than mutations in *SHH*, this has not been consistently demonstrated in the animal models, nor in humans (99). However, it is possible the mutations that result in the most severe phenotypes may be lethal in the embryonic or fetal period and hence have never been reported.

In contrast, mutations that result in increased signaling through the Hedgehog pathway may lead to the development of tumors or cancer-predisposition syndromes. Heterozygous loss-of-function mutations in *PTCH1* can result in the nevoid basal cell carcinoma (also known as basal cell nevus) syndrome (OMIM# 109400), which is characterized by multiple basal cell carcinoma in childhood or young adulthood, relative macrocephaly, ectopic calcification of the falx cerebri, jaw keratocysts, palmar or plantar pits, and in about 5% of individuals, medulloblastoma in childhood; cardiac and ovarian fibromas have also been reported in nevoid basal cell carcinoma syndrome (105). Somatic *PTCH1* mutations have also been identified in basal cell carcinoma samples from non-syndromic individuals who are otherwise healthy (OMIM# 605462). Germ line heterozygous loss-of-function mutations in *SUFU* that lead to inappropriate activation of the SHH pathway greatly increase the risk of desmoplastic medulloblastoma (OMIM# 155255). On the other hand, homozygous loss-of-function mutations in *RAB23* result in Carpenter syndrome (acrocephalopolysyndactyly type II) (OMIM# 201000), which is characterized by craniosynostosis (usually sagittal, coronal, and metopic sutures), obesity, brachydactyly, postaxial polydactyly of the hands, and insertional or preaxial polydactyly of the feet, cutaneous syndactyly in hands and feet, and congenital heart disease; cryptorchidism and hypoplastic external genitalia have been reported in males. There is no known increased risk for any cancers in Carpenter syndrome. It is believed that this syndrome is caused by inappropriate activation of GLI2 (*RAB23* usually inhibits GLI2) (94,106).

Heterozygous mutations in *GLI3* result primarily in two phenotypically distinct syndromes: Greig cephalopolysyndactyly syndrome (GCPS) (OMIM# 175700) and Pallister–Hall syndrome (OMIM# 146510); in addition, a small number of individuals with *GLI3* mutations have clinical features suggestive of orofaciocigital syndrome in which the clinical manifestations overlap with those of Pallister–Hall syndrome. GCPS is characterized by macrocephaly, hypertelorism, postaxial polydactyly of the hands, preaxial polydactyly of

the feet, and cutaneous syndactyly. Pallister–Hall syndrome is characterized by hypothalamic hamartoma, bifid epiglottis, laryngeal cleft, mesoaxial (insertional) polydactyly, anal atresia, and other visceral anomalies including adrenal insufficiency. This phenotypic dichotomy reflects the bifunctional role of GLI3 as a transcription activator and transcription repressor. Almost all the *GLI3* mutations that result in GCPS are loss-of-function mutations that occur mainly in either the 5′ or 3′ ends of the gene (5′ of cDNA nucleotide position 1998 or 3′ of cDNA nucleotide position 3481), with a smaller number of mutations in the middle part of the gene between nucleotide positions 1998 and 3481; the zinc finger DNA-binding domain is encoded by the nucleotides 5′ of position 1998 (i.e. in the amino-terminal of GLI3) while the transactivation domain is encoded by the nucleotides 3′ of position 3481 (i.e. in the carboxyl-terminal of GLI3). Recent data suggest that mutations 3′ of position 3481 may result in a milder GCPS (“sub-GCPS”) phenotype. The transcription activator function of GLI3 is therefore abrogated by all the mutations that lead to GCPS or sub-GCPS. In contrast, almost all *GLI3* mutations that result in Pallister–Hall syndrome are truncating mutations that occur in the middle part of the gene between cDNA nucleotide positions 1998 and 3481, which encode the normal GLI3 proteolytic processing site where full-length (activator) GLI3 is cleaved to form the repressor form of GLI3. Therefore, the *GLI3* mutations that lead to Pallister–Hall syndrome are those that result in the formation of a repressor form of GLI3 independent of HH-N binding to PTC1 (essentially a gain-of-function mutation for a repressor *GLI3*) (94,107,108). In contrast, isolated postaxial polydactyly type A (i.e. with a well-formed digit) and type B (i.e. poorly formed “pedunculated postminimi”) (OMIM# 174200) can also be caused by heterozygous *GLI3* mutations although the effects of these mutations on the GLI3 protein remain unclear (107,109).

It is believed that another member of the Hedgehog protein family, *DHH*, is expressed primarily in the gonads, although there is some expression in the neural sheaths as well. Homozygous loss-of-function mutations in *DHH* can result in 46,XY complete gonadal dysgenesis in which individuals with a 46,XY karyotype present as phenotypic females with bilateral streak gonads and in some individuals, bilateral gonadoblastoma (OMIM# 233420) (110,111). There has also been a report of a 46,XY female with partial gonadal dysgenesis (female external genitalia, immature uterus, and unilateral streak testicle) and minifascicular polyneuropathy who was found to have a homozygous mutation in *DHH* (112). However, no other patient with partial gonadal dysgenesis and minifascicular polyneuropathy has been found to have mutations in *DHH*.

Primarily expressed in prehypertrophic chondrocytes, *IHH* regulates the differentiation of chondrocytes, development of the growth plates, and endochondral

ossification, at least partly by inducing the expression of parathyroid hormone-related protein (PTHrP) (also known as parathyroid hormone-like hormone (PTHrH)). Heterozygous missense mutations in *IHH* that lead to reduced binding with its receptor (PTC1) and enhanced degradation within the lysosomes, but increased interactions with heparan sulfate proteoglycans and increased diffusion of the molecule away from the secreting cells (i.e. having both gain-of-function and loss-of-function effects), result in brachydactyly type A1 (OMIM# 112500) in which there is hypoplasia or absence of the middle phalanges of the digits, and short proximal phalanges of the thumbs and halluces (113–115). Homozygous mutations in *IHH* have been identified in two consanguineous families with acrocapitofemoral dysplasia (OMIM# 607778) in which there is brachydactyly, cone-shaped epiphyses in the middle and distal phalanges in the hands, premature fusion of the proximal femoral epiphyses leading to a short femoral neck, and short stature (116,117). One of these two homozygous mutations is close to the amino-terminal end while the other is close to the carboxyl-terminal end of the active *IHH* amino acid sequence (i.e. the amino-terminal domain of unprocessed *IHH*), in contrast to the heterozygous mutations that result in brachydactyly type A1, all of which occur in the middle part of the active *IHH* amino acid sequence (118). This suggests that these two different disorders are due to mutations in different domains (or subdomains) within the active *IHH* protein. Recently, it was shown that duplication of a conserved noncoding element upstream of *IHH* resulting in the overexpression of *IHH* can lead to syndactyly type 1 (OMIM# 185900), which is characterized by cutaneous syndactyly and synostosis of the distal phalanges in the hands and feet, or to Philadelphia-type craniosynostosis (OMIM# 601222), which is characterized by sagittal craniosynostosis and complete cutaneous syndactyly of the hands and feet with synostosis of the distal phalanges of the hands in a few of the affected individuals (119,120).

As discussed above, cholesterol is essential for the processing of the full-length Hedgehog proteins into the active signal-transducing HH-N ligands, and it has recently been shown that sterols are required for the activation of Smo in a mouse model, which suggests that defects in cholesterol synthesis and metabolism may affect the Hedgehog signal transduction pathway in the target cells (121). As such, the phenotypic manifestations of Smith–Lemli–Opitz syndrome (OMIM# 270400) in which there is a deficiency in 7-dehydrocholesterol reductase, the enzyme that catalyzes the last step in the cholesterol synthesis pathway, may be partly attributed to a secondary disruption in the Hedgehog signaling pathway (122).

### 15.8.2 Wnt Signaling Pathways

The Wnt signaling pathways regulate the transcription of specific developmental genes and are involved in

the development of the urogenital organs, limbs, skin, and other organ systems. There are two sets of pathways: the canonical Wnt pathway in which  $\beta$ -catenin is the key transcription co-regulator, and a number of different non-canonical Wnt pathways in which transcription is regulated by modulators such as RHOA (transforming protein RhoA) and calcineurin instead of  $\beta$ -catenin (11).

The Wnt ligands are cysteine-rich glycolipoproteins that undergo N-linked glycosylation after synthesis, which is required for the secretion of the ligand. Some Wnt molecules are palmitoylated (i.e. addition of palmitate) at specific cysteine residues, and in Wnt3a, palmitoleic acid is added to the serine residue at amino acid position 209 toward the C-terminal of the molecule. It has been suggested that the addition of palmitate facilitates binding of the ligand to its receptor while the addition of palmitoleic acid in Wnt3a is specifically required for its secretion. The palmitoleoylation of Wnt3a at serine 209 is believed to be mediated by PORCN (protein-cysteine N-palmitoyltransferase porcupine). PORCN may also be involved in the lipidation and secretion of other Wnt ligands (123,124).

The canonical Wnt pathway was the first Wnt signaling pathway to be elucidated and remains the best understood. Figure 15-21 illustrates the canonical Wnt pathway.

As illustrated in Figure 15-21, when a Wnt ligand is not bound to its specific receptor, excess  $\beta$ -catenin that is synthesized in the receptor cell is phosphorylated by the “destruction complex,” polyubiquitinated via the SCF-class E3 ubiquitin ligase BTRCP (beta-transducin repeat-containing protein) that only recognizes correctly phosphorylated  $\beta$ -catenin, and is degraded by 26S proteasomes in the cell. Transcription of the Wnt-regulated genes is normally repressed by the formation of a complex comprising either T-cell factor (TCF) or lymphoid enhancer-binding factor 1 (LEF1) together with TLE1 (the human homolog of *Drosophila groucho*) that binds to DNA, promoting the deacetylation of histones and compaction of chromatin. Note that there are at least four different TCF genes and multiple splicing variants in humans (123–125).

Binding of a specific Wnt ligand to its specific frizzled (Fz) transmembrane G protein-coupled receptor leads to the formation of a receptor complex with the low-density lipoprotein receptor-related protein LRP5 or LRP6 co-receptor. Disheveled (DVL1, and probably DVL2 and DVL3) is recruited to the Wnt–Fz–LRP5/6 complex. The cytoplasmic tail of LRP5 or LRP6 is then phosphorylated, resulting in the formation of an Axin 1-binding site. The destruction complex is thereby disrupted and free (unphosphorylated)  $\beta$ -catenin accumulates and enters the nucleus where it displaces TLE1, forms a complex with one of the TCF proteins or with LEF1, and recruits other transcription co-activators. Therefore, TCF proteins have

**FIGURE 15-21** The canonical Wnt signaling pathway. (A) In the absence of a signal, the destruction complex adenomatous polyposis coli (APC)-axin 1-glycogen synthase kinase 3 (GSK3)-casein kinase 1 (CK1) binds and phosphorylates non-cadherin-associated  $\beta$ -catenin, targeting it for destruction by the proteasome. In the nucleus, DNA-binding proteins of the TCF and lymphoid enhancer-binding factor 1 (LEF1) family are bound by transcriptional repressors (such as the transducin-like enhancer proteins (TLEs)). (B) The binding of a Wnt ligand to its frizzled receptor and lipoprotein receptor-related protein 5 (LRP5) or LRP6 co-receptor induces a change in conformation that results in phosphorylation of the co-receptor. This creates a high-affinity binding site for axin 1, causing disruption of the destruction complex.  $\beta$ -Catenin can then accumulate and associate with the TCF or LEF1 proteins, dislodging the TLE repressors and hence promoting transcriptional activation of a program of genes, including *MYC* and *axin 2*. *Axin 2* feeds back to inhibit the pathway by promoting the assembly of more destruction complexes. (McNeill, H.; Woodgett, J. R. *When Pathways Collide: Collaboration and Connivance among Signalling Proteins in Development*. Nat. Rev. Mol. Cell Biol. 2010, 11 (6), 404–413.)

the ability to both activate and repress transcription of Wnt-regulated genes, depending on the presence or absence of the Wnt ligands and hence  $\beta$ -catenin binding (123–125).

Table 15-4 lists some human diseases resulting from the gain (GOF) or loss (LOF)-of-function mutations in the canonical Wnt signaling pathway genes, as summarized by MacDonald et al. (124).

In the non-canonical Wnt pathway, Wnt ligands may bind to either the frizzled receptor (in what is also known as the frizzled-PCP (planar cell polarity) pathway), or other receptors including the tyrosine-protein kinase receptors such as ROR2 and RYK. Some Wnt ligands that activate the non-canonical Wnt pathway can inhibit the canonical Wnt pathway. For example, WNT5A is primarily a non-canonical Wnt ligand that binds to ROR2 and RYK; however, WNT5A also inhibits the canonical Wnt pathway by various mechanisms such as activating kinases that phosphorylate and inactivate TCF transcription factors, and competing with other Wnt ligands for binding to frizzled receptors (125). Heterozygous loss-of-function mutations in WNT5A have been found to be associated with autosomal dominant Robinow syndrome (OMIM# 180700), which is characterized by primarily mesomelic dwarfism, distinctive facial features such as hypertelorism, short nose with broad nasal bridge and anteverted nares, genitalia abnormalities such as short penis, clitoris, or

labia majora. In contrast, homozygous or compound heterozygous loss-of-function mutations in ROR2 result in autosomal recessive Robinow syndrome (OMIM# 268310) which is similar to, but phenotypically more severe than the autosomal dominant Robinow syndrome; rib anomalies including rib fusion and vertebral anomalies such as hemivertebrae are commonly seen in autosomal recessive Robinow syndrome. Of note, heterozygous gain-of-function mutation in ROR2 results in brachydactyly type B1 (OMIM# 113000) in which there is shortened middle phalanges and absent or severely hypoplastic distal phalanges and nails affecting particularly the fourth and fifth digits; mild distinctive facial features including hypertelorism may be observed (126).

### 15.8.3 Receptor Tyrosine Kinase Signaling Pathways

The receptor tyrosine kinases (RTKs) are a superfamily of transmembrane receptors that bind various growth factors, hormones, and other intercellular signaling molecules. There are at least 58 different RTKs in humans, subclassified into 20 subfamilies, as shown in Figure 15-22 (127). Many of the signaling pathways mediated by RTKs are involved in tissue morphogenesis and embryonic or fetal development. As such, germ line mutations in the genes that regulate these pathways can result in congenital malformation syndromes while

**TABLE 15-4 Human Diseases Associated with Mutations of the Wnt Signaling Components**

Gene	Function	Human Disease
PORCN	+ Wnt lipid modification/processing	LOF X-linked focal dermal hypoplasia
WNT3	+ Ligand for Wnt/ $\beta$ -catenin signaling	LOF tetra-amelia
WNT4	+ Ligand for Wnt/ $\beta$ -catenin signaling	LOF Müllerian duct regression and virilization
WNT5B	+ Ligand for Wnt/ $\beta$ -catenin signaling	(?) type II diabetes
WNT7A	+ Ligand for Wnt/ $\beta$ -catenin signaling	LOF Fuhrmann syndrome
WNT10A	+ Ligand for Wnt/ $\beta$ -catenin signaling	LOF odonto-onycho-dermal dysplasia
WNT10B	+ Ligand for Wnt/ $\beta$ -catenin signaling	LOF obesity
RSP01	+ Wnt agonist	LOF XX sex reversal with palmoplantar hyperkeratosis
RSP04	+ Wnt agonist	LOF autosomal recessive anonychia and hyponychia congenita
SOST	– LRP5/6 antagonist predominantly expressed in osteocytes	LOF high bone mass, sclerosteosis, Van Buchem disease
Norrin (NDP)	+ Specific ligand for FZD4 and LRP5 during eye development	LOF familial exudative vitreoretinopathy
LRP5	+ Wnt co-receptor	GOF hyperparathyroid tumors (alt. splicing), GOF high bone mass, LOF osteoporosis-pseudoglioma, LOF FEVR eye vascular defects
LRP6	+ Wnt co-receptor	LOF early coronary disease and osteoporosis
FZD4	+ Wnt receptor	LOF familial exudative vitreoretinopathy
Axin1	– Facilitates $\beta$ -catenin degradation; acts as a tumor suppressor	LOF caudal duplication, cancer
Axin2	– Facilitates $\beta$ -catenin degradation; acts as a tumor suppressor	LOF tooth agenesis, cancer
APC	– Facilitates $\beta$ -catenin degradation; acts as a tumor suppressor	LOF familial adenomatous polyposis, cancer
WTX	– Facilitates $\beta$ -catenin degradation; acts as a tumor suppressor	LOF Wilms tumor
$\beta$ -catenin (CTNNB1)	+ Primary Wnt effector; acts as an oncogene	GOF cancer
TCF4 (TCF7L2)	+ $\beta$ -catenin transcriptional partner	(?) type II diabetes

LOF, loss-of-function; GOF, gain-of-function.

Reproduced from Reference (124).

somatic mutations in some of these genes result in the development of various malignancies.

Each RTK comprises an extracellular ligand-binding domain, a single transmembrane helix, and a cytoplasmic catalytic domain with tyrosine kinase activity. Traditionally, it had been thought that the binding of the ligand to the receptor induces dimerization of the receptor and subsequent activation of the tyrosine kinase domains. However, more recent studies suggest that some RTKs form dimers and oligomers on cell membranes even in the absence of ligand binding, but it is the binding of specific ligands to the specific dimeric or oligomeric receptors that results in tyrosine kinase activity; some RTKs form homodimers (i.e. with the same type of RTK receptor) but others form heterodimers between different RTKs within the same subfamily. Monomeric RTKs are almost always inactive due to intramolecular (i.e. *cis*) autoinhibition of the tyrosine kinase domains; dimerization or oligomerization along with ligand binding releases this autoinhibition by various mechanisms including (i) trans-autophosphorylation of the activation loop that blocks the enzymatic site and prevents substrate binding as well (i.e. phosphorylation of specific tyrosine residues in the activation loop of the “partner” co-receptor), (ii)

phosphorylation of specific tyrosine residues in the juxta-membrane region (i.e. between the transmembrane helix and the intracellular tyrosine kinase domain), and (iii) direct allosteric activation through contact between the dimers or oligomers. Signal transduction through RTKs is therefore regulated by their distribution and density on the cell surface. Moreover, each RTK usually binds only one or a small subset of ligands (127,128).

When the tyrosine kinase domains have been activated, specific tyrosine residues in the cytoplasmic domains are phosphorylated. These phosphotyrosine residues can recruit and provide docking sites for adaptor (also known as docking) proteins that contain Src homology-2 (SH2) or PTB domains; these adaptor proteins can, in turn, be phosphorylated at specific tyrosine residues by the tyrosine kinase in the RTK on which they have docked. Each adaptor protein bound to an RTK can activate a variety of intracellular signaling cascades including the RAS–MAPK, PI3K–AKT, PLC $\gamma$ –PKC, and JAK–STAT pathways. Some of these signaling cascades can also be activated by the direct binding of specific molecules to the phosphotyrosine residues in the cytoplasmic domains directly. Activation of these pathways usually results in alteration in gene transcription (127,128).

**FIGURE 15-22** The 20 subfamilies of human RTKs, shown schematically with the family members listed beneath each receptor. Structural domains in the extracellular regions, identified by structure determination or sequence analysis, are indicated according to the key. The intracellular domains are shown as red rectangles. (Lemmon, M. A.; Schlessinger, J. *Cell Signaling by Receptor Tyrosine Kinases*. Cell 2010, 141 (7), 1117–1134.)

(Note abbreviations: RAS, “Rat sarcoma,” a family of GTP/GDP-binding GTPases whose members include HRAS, KRAS, NRAS; MAPK, mitogen-activated protein kinase, which is a family of serine/threonine protein kinase; PI3K, phosphoinositide 3-kinase; AKT, not an abbreviation but named after a thymoma cell line derived from the AKR mouse strain—it is a serine/threonine protein kinase, also known as protein kinase B; PLC $\gamma$ , phospholipase C- $\gamma$ ; PKC, protein kinase C; JAK, Janus kinase; STAT, signal transducer and activator of transcription.)

A simplified view of RTK signal transduction through adaptor proteins is illustrated in Figure 15-23.

The activity of the RTK-mediated signaling pathways is partly regulated by a series of positive and negative feedback loops. Positive feedback resulting in sustained or increased tyrosine kinase activity may be achieved through either stimulation of kinase activity or inhibition of protein tyrosine phosphatases (PTPs) that normally reverse autophosphorylation of the cytoplasmic domains, both of which processes may be induced by ligand binding. Negative feedback may be accomplished by direct activation of PTPs. For example, SHP1 (encoded by *PTPN6*) and SHP2 (encoded by *PTPN11*) are SH2 domain-containing PTPs that are recruited to dephosphorylate activated epidermal growth factor

**FIGURE 15-23** The docking (i.e. adaptor) protein FGF receptor substrate-2 (FRS2 $\alpha$ ) forms a complex with activated FGF or nerve growth factor (NGF) receptors via its PTB. The activated RTK phosphorylates FRS2 $\alpha$  on multiple tyrosines, and the resulting phosphotyrosines recruit multiple growth factor receptor-bound protein 2 (Grb2) and Shp2 (also known as tyrosine-protein phosphatase non-receptor type 11, encoded by *PTPN11*) molecules. This brings a second docking protein, GRB2-associated-binding protein 1 (Gab1), into the complex. Gab1 is tyrosine phosphorylated and recruits additional signaling proteins, including PI3K. PI3K initiates a positive feedback loop in which phosphatidylinositol (3,4,5)-triphosphate (PIP3), generated by PI3K, recruits more Gab1, leading to further PI3K activation. (Abbreviations: PIP2, phosphatidylinositol (4,5)-biphosphate, phosphorylation of which by PI3K results in PIP3; PDK, 3-phosphoinositide-dependent protein kinase; SOS, son of sevenless; ERK, extracellular signal-regulated kinase, a member of the mitogen-activated protein kinase (MAPK) family.) (Lemmon, M. A.; Schlessinger, J. *Cell Signaling by Receptor Tyrosine Kinases*. Cell **2010**, 141 (7), 1117–1134.)

receptor (EGFR). In the RAS-MAPK/ERK (extracellular signal-regulated kinase) cascade, MAPK/ERK directly phosphorylates SOS, impeding its interactions with GRB2; MAPK/ERK also directly phosphorylates and reduces the activity of the RAF serine/threonine protein kinase that activates MAPK/ERK via an MAPK kinase (MAPKK), forming negative feedback loops. Some activated RTKs such as EGFR are degraded intracellularly via ubiquitination, which is an important mechanism that prevents excessive signaling through those RTKs (127).

It should also be noted that some RTKs such as EGFR and the neurotrophic tyrosine kinase receptor subfamily can be internalized into endosomes and the signaling pathways that they activate depend on whether the receptors are bound to the plasma membrane or to the intracellular endosomes (128). In some RTKs such as MET, trafficking of the receptor to a perinuclear endosome is required only for the phosphorylation of specific, but not all, proteins (127).

#### 15.8.4 RAS-MAPK/ERK Pathway

It has now been established that heterozygous mutations in genes that regulate the RAS-MAPK/ERK pathway, which is one of the intracellular signaling pathways mediated through the RTKs, result in a group of congenital malformation syndromes known as the “RASopathies,” some of which are listed in [Table 15-5](#). Almost all of these mutations result in prolonged or overactivation of the RAS-MAPK/ERK pathway; gain-of-function mutations were identified in the genes that encode proteins that promote the activation of the pathway while loss-of-function

Legius syndrome	611431	<i>SPRED1</i>

<sup>a</sup>**Bold:** Genes that are more frequently mutated in those syndromes.

Table adapted and modified from Zenker, M. Clinical Manifestations of Mutations in RAS and Related Intracellular Signal Transduction Factors. *Curr. Opin. Pediatr.* 2011, 23 (4), 443–451.

mutations were found in genes that encode proteins that repress the activity of the pathway. Many of these syndromes share some common but variable clinical features such as postnatal growth retardation, relative macrocephaly, learning or intellectual disabilities, congenital structural heart defects, skin lesions, and specific malignancies. Of note, germ line mutations that result in these syndromes appear to be “less activating” than somatic mutations found in tumors. The clinical manifestations

of these syndromes were recently reviewed by Tartaglia and Gelb (129) and Zenker (130).

MAPKs is a group of at least four distinct serine/threonine kinases: ERK1/ERK2 (also known as MAPK3/MAPK1 respectively), Jun amino-terminal kinases (JNK1/2/3—also known as MAPK8/9/10 respectively), p38 proteins (p38 $\alpha$ /p38 $\beta$ /p38 $\gamma$ /p38 $\delta$ —also known as MAPK14/11/12/13), and ERK5 (also known as MAPK7), each of which phosphorylates one or more distinct transcription factors; some transcription factors can be phosphorylated by different MAPKs. Each

**FIGURE 15-24** On recruitment to activated growth factor receptors, guanine nucleotide exchange factors such as SOS1 activate RAS through facilitating the exchange of GDP by GTP. Active GTP-bound RAS initiates the RAS-MAPK/ERK pathway, leading to the activation of ERK. RAS is converted back to its inactive state by hydrolysis of GTP to GDP through its intrinsic GTPase activity, which is augmented by GTPase-activating proteins such as neurofibromin (NF1). NF1 is thus a negative regulator of RAS signaling. SHOC2 and SPRED1 are positive and negative modulators, respectively, at the level of the RAS–RAF interaction. CBL protein is an E3 ubiquitin (Ub) ligase that can recognize tyrosine-phosphorylated substrates and hence negatively modulates RTK signal transduction. (Zenker, M. *Clinical Manifestations of Mutations in RAS and Related Intracellular Signal Transduction Factors*. *Curr. Opin. Pediatr.* 2011, 23 (4), 443–451.)

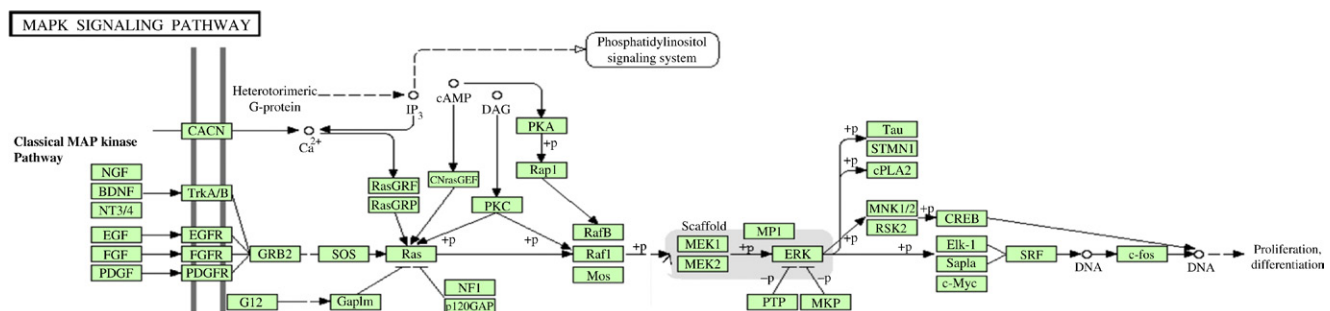

group of MAPKs has to be activated via phosphorylation by a specific MAPKK: MAPK/ERK kinases 1 and 2 (MEK1 and MEK2, official symbols: MAP2K1 and MAP2K2) both activate ERK1/ERK2, MAPKKs 3/6 (MKK3/6, official symbols: MAP2K3/6 respectively) activate the p38 proteins, MAPKKs 4/7 (MKK4/7, official symbols: MAP2K4/7 respectively) activate the JNK proteins, and MAPK/ERK kinase 5 (MKK5, official symbol: MAP2K5) activates ERK5. Each of these MAPKKs may be activated by one or more distinct MAPK kinase kinases; in the RAS-MAPK/ERK pathway, these would be the RAF family kinases such as BRAF and RAF1 (131–134).

The RAS-MAPK/ERK pathway is activated when specific ligands bind to one of the RTKs that mediates this pathway such as the neurotrophic tyrosine kinase receptor types 1 and 2 (also known as the “high-affinity nerve growth factor receptor” and “BDNF/NT-3 growth factors receptor,” respectively), EGFR, FGFR (fibroblast growth factor receptor), and PDGFR (platelet-derived growth factor receptor) (132). GRB2 then binds to specific tyrosine residues in the cytoplasmic component of these RTKs that have been phosphorylated by the activated tyrosine kinase domains. This leads to the recruitment and activation of SOS1, a guanine nucleotide-exchange factor. SOS1 catalyzes the conversion of GDP to GTP, thereby activating the RAS family of GTPases. Activated GTP-bound RAS then activates the RAF family of kinases that are the MAPKs in the RAS-MAPK/ERK signaling pathway. The activity of RAS is moderated by its own intrinsic GTPase activity which converts it back to the inactive GDP-bound form, and by repressors such as neurofibromin encoded by *NF1* (129,130). A simplified diagram of this pathway is shown in Figure 15-24.

A more comprehensive diagram illustrating the various ligands and receptors in the RAS-MAPK/ERK pathway is shown in Figure 15-25.

### 15.8.5 Homeobox Genes and Anterior–Posterior Patterning

The HOX gene families are members of the ANTP class in the homeobox superfamily of genes. The genes

**FIGURE 15-25** Note: Interactions with the JNK and p38 MAPK pathways have been omitted for simplicity. (Kanehisa Laboratories (KEGG: Kyoto Encyclopedia of Genes and Genomes) MAPK signaling pathway: *Homo sapiens* (human), <http://www.genome.jp/kegg/pathway/hsa/hsa04010.html>, (accessed Jun 2, 2012).)

in the homeobox superfamily are characterized by the presence of a highly conserved 180bp sequence close to the 3' end of these genes; this sequence, known as the homeobox, encodes the homeodomain, which is a 60-amino acid DNA or mRNA-binding helix-turn-helix motif that can regulate transcription and translation by binding to homeobox responsive elements in DNA or mRNA (11,135). There are four clusters of HOX genes in humans (HOXA, HOXB, HOXC, and HOXD) due to genome duplication during evolution, resulting in a total of 39 HOX genes. The genes within each cluster lie close to one another within a given chromosomal segment. As described in Section 15.5 above, genes in the equivalent positions within each cluster are derived from the same common ancestral gene and therefore share very similar structures and functions (i.e. paralogous with one another across all four clusters), although none of the clusters contains every paralogous gene. There is some functional redundancy among members within each paralogous group. In humans, there are 13 paralogous HOX groups, classified into seven HOX gene families, namely HOX1, HOX2, HOX3, HOX4, HOX5, HOX6-8, and HOX9-13 (136,137). The HOX genes are partly responsible for determining the anterior–posterior axis in the developing embryo and regulate the formation of musculoskeletal structures in each body segment. Within each cluster, the HOX genes are arranged sequentially

such that the genes that are expressed earliest in development (e.g. HOXA1, HOXB1, and HOXD1) are at the 3' end while those that are expressed later in development (e.g. HOXA13, HOXB13, HOXC13, and HOXD13) are at the 5' end of the chromosomal strands. The HOX genes are shown in Figure 15-26, depicted in the order in which they are transcribed within each cluster and their chromosomal loci.

While the hindbrain is specified by the most anterior (and hence earliest expressing) HOX genes such as *HOXA1*, *HOXA2*, and *HOXB2*, the anterior–posterior and dorsal–ventral axes of the forebrain and midbrain are specified by the OTX (orthodenticle homolog) gene family, which is a member of the PRD class in the homeobox superfamily, and by the EMX (empty spiracles homolog) gene family, which is a member of the ANTP class in the homeobox superfamily, just like the HOX gene families. The OTX genes are expressed in both the forebrain and the midbrain before the EMX genes are expressed, with *OTX2* being the first of these four genes to be expressed, followed by *OTX1*; expression of these two genes is restricted to the forebrain and the midbrain. Both OTX genes are also expressed in the developing eye and possibly other sensory organs in the head. *EMX2* and *EMX1* are then expressed but only in the forebrain and in that order. In addition, *VAX1* and *VAX2* in the VAX (ventral anterior homeobox) gene family interact with *EMX2*

**FIGURE 15-26** The four clusters of HOX genes in mammals and the expression patterns (inferred from mouse expression studies) of the orthologous genes in a stage 19 human embryo. The colored fields depict the anterior-most domains of expression. The posterior boundaries of the expression domains may overlap in more caudal regions. Note the shift in the anterior expression boundaries between the nervous system and the segmented mesoderm, which nevertheless preserves the relative order of gene expression. Several of the posterior *HOXA* and *HOXD* genes are also expressed in the limb primordia, as indicated by the yellow coloration. (Veraksa, A.; Del Campo, M.; McGinnis, W. *Developmental Patterning Genes and their Conserved Functions: From Model Organisms to Humans*. Mol. Genet. Metab. 2000, 69 (2), 85–100.)

and *EMX1*, respectively; the *VAX* gene family is also a member of the ANTP class in the homeobox superfamily (139,140). Details of the other homeobox genes involved in the patterning of the forebrain have been reviewed by Wigle and Eisenstat (140).

Some HOX paralogous groups regulate the development of entire sclerotomal regions in the axial domain such as vertebrae, ribs, and muscles defined during somitogenesis. For example, the HOX paralogous group 9 (i.e. *HOXA9*, *HOXB9*, *HOXC9*, and *HOXD9*) is required for the development of “floating ribs”; the HOX paralogous groups 10 and 11 (i.e. *HOXA10*, *HOXC10*, *HOXD10* and *HOXA11*, *HOXC11*, *HOXD11*) are required for the proper formation of the sacrum. Some HOX genes in the anterior and central paralogous groups in conjunction with members of the CDX (caudal type homeobox) gene family comprising *CDX1*, *CDX2*, and *CDX4*, may stimulate the growth and hence length of the axial skeleton. This process may be mediated through the canonical Wnt signaling pathway. In contrast, members of the HOX paralogous group 13 (i.e. *HOXA13*, *HOXB13*, *HOXC13*, and *HOXD13*) can inhibit axial growth (141).

Some of the syndromes that result from mutations in the various homeobox genes described above are shown in Table 15-6, all of which are due to heterozygous mutations in the associated genes.

It should be noted that regulation of gene expression by homeobox genes is not the only mechanism for the determination of the anterior–posterior axis during embryonic development. A concentration gradient of specific molecules including FGF8 and RA that is highest in the posterior region and lowest in the anterior region

of the embryo also influences the proper development of the anterior–posterior axis (11).

## 15.9 ORGANOGENESIS

### 15.9.1 Heart

A functioning cardiovascular system is required once the oxygenation needs of the embryo cannot be met because of the increasing size of the developing embryo. Although the neural crest provides some cells to the heart, the majority of the tissues of the heart are derived from mesoderm (142,143). The first step in the formation of the embryonic heart is the fusion of a pair of endocardial tubes derived from the splanchnic mesoderm, which starts to beat at around 22–23 days even before it has fully formed, making it the first functional organ in the embryo. As the tube enlarges, constrictions mark the division into the truncus arteriosus, bulbus cordis, ventricle, atrium, and sinus venosus from rostral to caudal. The bulbus cordis is incorporated into the mature right ventricle. The conus cordis (derived from the bulbus cordis), along with the truncus arteriosus, forms the outflow tracts of the ventricles. The sinus venosus receives venous blood. As the heart tube grows, it bends and forms the cardiac loop. The looping results in left–right asymmetry and in the different parts of the heart assuming their correct relative spatial orientations. The heart tube loops such that the cranial portion moves ventrally and to the right, while the atria move dorsally and to the left. The result is that the atrium and sinus venosus lie dorsal to the truncus arteriosus, bulbus cordis, and ventricle.

**TABLE 15-6 Some of the Syndromes Associated with Mutations in Homeobox Genes**

	OMIM# (Syndrome)	Gene Mutated	Major Tissues/Organs Involved
Bosley–Salih–Alorainy syndrome	601536	<i>HOXA1</i>	CN (Duane syndrome), ears in both syndromes; brain (developmental delay, central hypoventilation (hindbrain)) and heart especially in ABDS
Athabaskan brain stem dysgenesis syndrome (ABDS)			
Microtia, hearing impairment, and cleft palate	612290	<i>HOXA2</i>	Ears, mouth
Congenital vertical talus	192950	<i>HOXD10</i>	Feet
Radioulnar synostosis with amegakaryocytic thrombocytopenia	605432	<i>HOXA11</i>	Forearms, fingers, pelvis, bone marrow
Hand–Foot–Uterus (also known as Hand–Foot–Genital) syndrome	140000	<i>HOXA13</i>	Hands and feet (thumbs and big toes), external and internal genitalia, kidneys
Brachydactyly type D	113200	<i>HOXD13</i>	Thumbs and big toes
Brachydactyly type E1	113300	<i>HOXD13</i>	Fingers and toes
Brachydactyly–Syndactyly	610713	<i>HOXD13</i>	Hands and feet
Syndactyly type V	186300	<i>HOXD13</i>	Hands and feet
Synpolydactyly-1 (syndactyly type II) with or without foot anomalies	186000	<i>HOXD13</i>	Hands and feet
Microphthalmia with retinal dystrophy, optic nerve hypoplasia, pituitary dysfunction, developmental delay	610125	<i>OTX2</i>	Brain, CNs, eyes
Combined pituitary hormone deficiency	613986	<i>OTX2</i>	Pituitary gland
Schizencephaly	269160	<i>EMX2</i>	Brain

**FIGURE 15-27** Development and septation of the heart. (A and B) Sagittal sections of the heart. (C and D) Coronal sections of the heart. Arrows indicate the flow of blood through the heart.

The atrioventricular (AV) canal connects the common atrium and the early embryonic ventricle. The AV canal is divided by endocardial cushions that arise at the superior and inferior borders of the canal in the fourth week. The cushions also form the AV valves. The endocardial cushions grow across the AV canal and fuse, creating left and right AV canals. Regions of the endocardial cushions then fuse with both atrial and ventricular septa. If both atrial and ventricular septa and the medial AV valve leaflets are incomplete due to failure of fusion of the cushions, a persistent AV canal can result, as may sometimes be seen in association with Down syndrome.

In the atria, the septum primum, a thin membrane, grows from the dorsal roof of the common atrium toward the AV canal. Its forward edge creates an opening between the septum and the endocardial cushions, the ostium primum. As the ostium primum is being closed by fusion of the septum primum and the fused endocardial cushion tissue, perforations form in the septum primum by programmed cell death. The coalescence

of these holes forms the ostium secundum. A septum secundum then forms to the right of the septum primum, growing from the roof of the atrium, covering the ostium secundum. However, the septum secundum forms an incomplete division of the atria. The opening between the two septa is the foramen ovale. Defects in closure of the ostium primum or ostium secundum result in atrial septal defects. Ostium secundum defects are relatively common and can be due to defects in formation of the septum primum or the septum secundum.

The muscular interventricular septum is formed for the most part as a result of cavitation of the right and left ventricular chambers. Final closure of the ventricular septum is brought about by fusion of the muscular septum with endocardial cushion tissue. This tissue also fuses with the aorticopulmonary septum. This final region of ventricular septation is the membranous part of the interventricular septum. Ventricular septal defects are the most common congenital heart defect, and membranous defects are the most common form.

The truncus arteriosus divides to form the proximal portion of the aorta and pulmonary artery. The septum between these great vessels forms by fusion of bilateral ridges. Neural crest cells migrate from the pharyngeal arches to participate in the formation of this septum. Failure of the ridges to fuse results in persistent truncus arteriosus. This is usually associated with a ventricular septal defect. Unequal division of the outflow vessels can lead to tetralogy of Fallot, which is characterized by (i) right ventricular outflow obstruction, resulting from a narrow pulmonary orifice, (ii) ventricular septal defect, (iii) overriding aorta, and (iv) hypertrophy of the right ventricle (which is secondary to the right ventricular outflow obstruction). The genetic and epigenetic regulations of cardiogenesis have recently been reviewed by López-Sánchez et al. (144), van Weerd et al. (145), and Miquerol and Kelly (146). The development of the heart is shown in Figure 15-27.

### 15.9.2 GI Tract

The epithelial lining of the GI tract is derived from the endoderm, the connective tissue and smooth muscle are derived from the mesoderm, and the enteric nervous system is derived from the ectoderm. The primitive gut is defined by the oropharyngeal membrane rostrally and the cloacal membrane caudally. The mesodermally derived and endodermally derived components induce each other's development; the different functional portions of the GI tract (e.g. stomach, small intestine, large intestine) are partly due to regional differences in these interactions.

The foregut, midgut, and hindgut are each supplied by different blood vessels. The foregut gives rise to the pharynx, respiratory system, liver, esophagus, stomach, and proximal duodenum. The respiratory diverticulum forms from the ventral surface of the endodermal tube. A division forms between the developing esophagus and the trachea. An error in normal development of the tracheoesophageal

septum can lead to esophageal atresia. Diverticula that will form the liver, biliary apparatus, and pancreas arise from the distal portion of the foregut (147–149).

The midgut forms the distal part of the duodenum, the jejunum, the ileum, the cecum and appendix, the ascending colon, and the proximal two thirds of the transverse colon. The connection between the midgut and the yolk sac, the vitelline duct, is located within the umbilical cord. Rapid growth of the midgut forms a loop of gut. At the sixth week, the midgut then grows outside of the abdominal cavity into the umbilical cord and the yolk stalk. This physiologic herniation of the midgut is required for normal growth of the intestines as there is insufficient space in the abdominal cavity at this time to contain the growing intestines. During the 10th week, the midgut returns to the embryonic abdomen. Abnormalities in the retraction process resulting in persistence of the herniation of the midgut into the umbilical cord can result in omphalocele.

The hindgut gives rise to the distal one third of the transverse colon, the descending colon, the rectum, and the proximal portion of the anal canal. It also gives rise to the epithelium of the bladder and most of the urethra. The caudal part of the hindgut is continuous with the cloaca, which is divided by the urogenital septum into the urogenital sinus (which gives rise to the bladder and urethra) and the rectum. Incomplete septation of the hindgut can cause a persistent cloaca.

The endodermal tube is initially hollow. Many parts of it then become solid as the endodermal epithelium rapidly proliferates. Recanalization reopens the lumen by weeks 8–10. Stenosis or atresia of the GI tract can result from failure to recanalize, especially in the proximal duodenum. More caudal atresias or stenosis may be due to compromise of the vascular supply, resulting in narrowing of the lumen.

The distal foregut and the midgut undergo a series of rotations to reach their adult orientation. The stomach rotates such that the dorsal side forms the greater curvature while the ventral side forms the lesser curvature. Thus the original left side becomes ventral while the original right side becomes dorsal. Rotation of the stomach causes the duodenum to adopt a C-shaped loop. While the midgut loop is in the umbilical cord and outside of the abdominal cavity, it begins to rotate around the axis of the superior mesenteric artery. A total rotation of 270° counterclockwise occurs, and this rotation fixes the placement of the stomach, duodenum, and intestines. Abnormal rotation can result in twisting of the intestines (volvulus) and may compromise the blood supply to that region. The genes involved in the development of the intestines have been reviewed by Noah et al. (150).

### 15.9.3 Genitourinary System

The urinary and internal genital systems have a common origin, being derived primarily from the intermediate mesoderm (151). Growth of the mesoderm creates the urogenital ridge, which forms on either side of the dorsal aorta. It gives rise to the nephrogenic cord and

the genital ridge. Three successive pairs of kidneys form from this mesoderm. They are termed the pronephros, mesonephros, and metanephros. The pronephros is rudimentary. In addition to the mesonephric duct, the mesonephric kidney gives rise to the mesonephric tubules, which open into the mesonephric duct. The metanephros gives rise to the adult kidney. The permanent kidney begins to form at 5 weeks gestation and becomes functional toward the end of the first trimester. It arises from inductive interactions between the ureteric bud (a mesonephric duct diverticulum) and the metanephric cap (metanephric mesoderm). The cells of the cap form small vesicles, which give rise eventually to the nephron, the excretory unit of the kidney. The ureteric bud forms the collecting system of the kidney, as well as the ureters. The kidneys initially develop in the pelvic region ventral to the sacrum but assume a position in the abdomen by the ninth week. This “migration” is primarily due to growth of the abdomen and pelvis.

Between 4 and 7 weeks, the urorectal septum divides the cloaca into the anorectal canal and the urogenital sinus. The urogenital sinus gives rise to the urinary bladder and prostatic and membranous portions of the urethra and becomes connected to the rest of the urinary system.

The kidneys may be united at their lower poles, forming a single horseshoe kidney. Horseshoe kidneys do not properly ascend (pelvic kidney). Renal agenesis is due to degeneration of the ureteric bud. Without the bud, the metanephric cap does not develop and no nephrons are formed. The genes involved in the development of the kidneys have been reviewed by Potter et al. (152), and Song and Yosypiv recently reviewed the genetic bases of congenital renal malformations (153).

### 15.9.4 Central Nervous System

The human brain develops from a uniform-appearing pseudostratified neuroepithelium that is present after initial induction of the neural plate/tube. The understanding of brain development while extremely rudimentary, illustrates lessons that can be useful in diagnosing human genetic diseases. Brain development can be broken down to five basic steps: tissue/cellular specification, proliferation followed by final differentiation, neuronal migration, axonal outgrowth/target finding and finally synaptogenesis/network modification. Each of these processes will be discussed briefly and illustrated by examples in human disease when the processes go awry. Disorders that lead to structural disruption of the brain are easier to recognize and categorize clinically and hence it is easier to identify their underlying genetic causes. Genetic disorders that affect only cognition or behavior are generally more difficult to definitively categorize due to the relative lack of phenotypic heterogeneity. It is also more difficult to determine the pathophysiology of cognitive dysfunction because of the complexities of modeling these diseases in animals.

The nervous system can be divided into three categories, central, peripheral, and enteric nervous systems. Only

the central nervous system that includes the brain and the spinal cord will be discussed here (see (154,155) for more details on the peripheral nervous system and (156–158) for enteric nervous system). The understanding of human brain development is greatly facilitated by the study of model organisms, including mouse, rat, chick, *Drosophila*, *C. elegans*, and zebrafish. There are many similarities between the development of model organisms and the human brain, but there are key differences as well. Therefore, one should be wary of being too dogmatic when applying lessons from animal studies to human diseases.

The purpose of the brain is to allow an individual to perceive stimuli, interpret the information, and interact with the environment. Environmental information is received by sensory organs in the peripheral nervous system (except the retina, which is part of the central nervous system), relayed to the central nervous system, processed, and either a reflex action is made or information is interpreted and action taken. At a cellular and highly simplified level, information flows into a neuron through dendrites or the cell body at synapses as either a change in voltage potential via flow of ions across the plasma membrane or as a biochemical signal via second messengers. This information is summed in the cell body of a neuron and if a critical electrical depolarization threshold is reached, an electrical action potential is transmitted down the axon via flow of ions through voltage-sensitive channels. Neurons generally communicate from an axonal terminal to its target via chemical synapses. In addition to neurons, many other cells types in the brain play critical functions as well. Oligodendrocytes help increase the speed of an action potential down an axon and form the white matter of the brain. Astrocytes perform a myriad of critical support roles. Pathogenic oligodendrocytic and astrocytic functions result in numerous human diseases (see (159) for more details on basic concepts of neuronal activity and cellular function).

The brain is organized into different structures that can be separated into divisions along the neuroaxis from rostral (beak or nose) to caudal (tail) regions and the proximate timing of developmental events can be seen in Table 15-7 (160–164). The most rostral region includes the forebrain (prosencephalon, which is further subdivided into telencephalon and diencephalon), followed by the midbrain (mesencephalon), the hindbrain (rhombencephalon, which is composed of metencephalon and myelencephalon), and finally the spinal cord. Each anatomic region will be used to illustrate important lessons to understand the basic neuronal development as well as genetic diseases. Many developmental principals are used in more than one region. However, some developmental patterns or mechanisms appear to be unique to a single region.

**15.9.4.1 Spinal Cord.** The spinal cord is one the simplest structures within the central nervous system but understanding its development offers insights into the complexity of understanding brain development. Critically, it has the same basic dorsal–ventral pattern for its entire length, with motor neurons located toward and their axons

**TABLE 15-7** Timing of Human Brain Development

Event	Gestation Age
Neural plate forms	16th day
Longitudinal groove forms	20th day
Neural tube closure start at second to seventh somite	22nd day
Neuromeres start to form in hindbrain	22nd day
Forebrain induction	Third week
Cerebellum formation starts	Fourth week
Purkinje cells are born	5–6 weeks
Cerebral cortex start to expand	6 weeks
Ganglionic eminences form	6–7 weeks
Cerebral cortex preplate forms	6–7 weeks
Cortical plate (CP) forms	7–10 weeks
Cerebral cortical neurogenesis	7–18 weeks
Neuronal migration into CP (including GABAergic neurons)	7–28 weeks
Corpus colossal fiber start to cross midline	12 weeks
Myelination	
Most of cerebral cortex	First year of life
Cerebral commissures	First half of first decade
Intracortical association	Through second decade
Synapse dynamics (visual cortex)	
Formation	Third trimester to 5 years
Pruning	5 years to second decade

O., Development and developmental disorders of the human cerebellum. *J. Neurol.* 2003, 250 (9), 1025–1036.

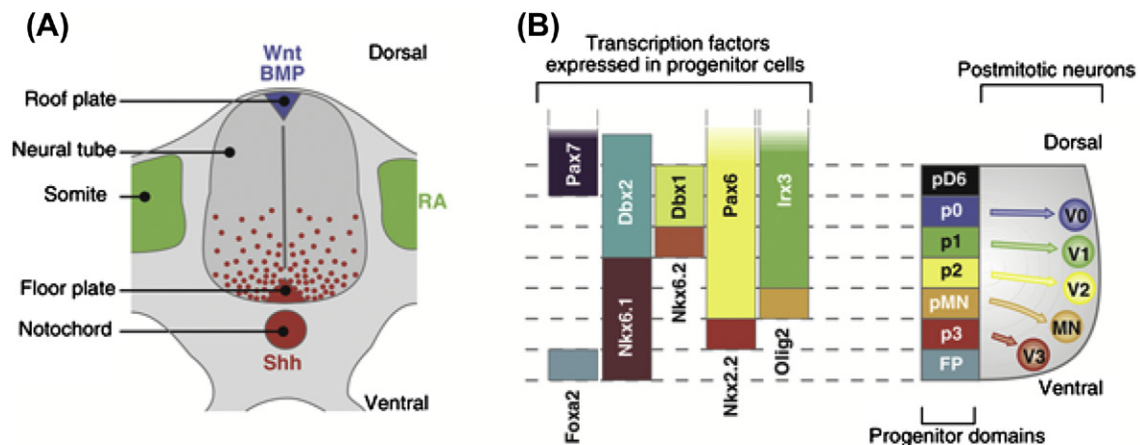

exiting through the ventral surface while sensory nerves enter the dorsal regions; a series of interneurons are present throughout the dorsal–ventral axis (Figure 15-28). SHH (see Section 15.8.1) is involved in the induction of the neural tube establishes a gradient within the developing spinal cord that forms a combinatorial code of transcription factors that produce the various cell types in the ventral region (Figure 15-29) (167–169). The factors produced in the roof plate (Wnt and BMP) may play a similar role for the dorsal progenitor cell types (169). It has also become clear that motor neurons at specific spinal cord levels along the rostral–caudal axis are predestined to target specific muscle groups, demonstrating neuronal specification in the rostral–caudal (170,171).

**15.9.4.2 Hindbrain.** Within the hindbrain resides the control of many basic functions including CN nuclei that help to control eye movements (CN III, IV, VI), facial sensation and muscles of mastication (CN V) derived from the first pharyngeal arch, muscles of facial movements

**FIGURE 15-28** A diagram of spinal cord showing localization of white matter tracts (not addressed here) and regions of neurons within the gray matter. The gray matter is subdivided into different regions (I–X) that have different functions. For instance, the motor neurons localized in IX innervate skeletal muscle. (DeArmond, S. J.; Fusco, M. M.; Dewey, M. M. *Structure of the Human Brain, a Photographic Atlas*. Oxford University Press: New York, 1974; Duus, P. *Topical Diagnosis in Neurology*, 3rd ed., Thieme: New York, 1998.)

**FIGURE 15-29** (A) Schematic of spinal cord induction. Shh (red) is secreted by the notochord and floor plate (i.e. ventrally), retinoic acid (RA) (green) is secreted by the somites that flank the neural tube, and bone morphogenetic proteins (BMP) and Wnt gene family (blue) are produced at the roof plate dorsally. Shh establishes a gradient from ventral to dorsal within the ventral neural tube (red dots). This Shh gradient regulates the differential expression of specific transcription factors in neural progenitor cells within the ventral region of the developing neural tube, as shown in (B): *Pax7*, *Pax6* and *Irx3* are repressed by Shh signaling while *Dbx1*, *Dbx2*, *Nkx6.1*, *Olig2*, *Nkx2.2* and *Foxa2* require Shh signaling for their expression. (B) This combinatorial code of transcription factor expression establishes progenitor domains in the ventral region that will produce various interneuron cell types, V0–V3 or motor neurons (MN). A similar mechanism for regulating the expression of genes in the dorsal region may be mediated via Wnt and BMP (not shown). FP, floor plate. (Dessaud, E.; McMahon, A. P.; Briscoe, J. *Pattern Formation in the Vertebrate Neural Tube: A Sonic Hedgehog Morphogen-Regulated Transcriptional Network*. *Development* 2008, 135 (15), 2489–2503.)

(CN VII) derived from the second pharyngeal arch, hearing and equilibrium (CN VIII), salivation and muscles of the pharynx (CN IX) derived from the third pharyngeal arch, pharynx and larynx (CN X) derived from the fourth pharyngeal arch, and tongue movements (CN XII). The hindbrain also regulates control of breathing, coordination of movements through cerebellar-related nuclei and many other functions (166). The earliest visible specification of the hindbrain is the formation of rhombomeres (neuromeres) (Figure 15-30), which is regulated by many processes including segmentation genes such as members of the Hox gene families (see Section 15.8.5). These transcription factors are expressed prior to the transient morphological appearance of rhombomeres. Instead of discussing the development of each brain stem nucleus, we will illustrate principles of brain stem development (see (172,173) for review of hindbrain development). Rhombomeres define anatomical segments within which

different cell types are born (Figure 15-31). Like the spinal cord, there are also ventral–dorsal differences. The most ventral region, known as the basal plate and nearest to the inducing notochord, produces motor neurons while the dorsal neural tube, known as the alar plate, produces sensory neurons. Not surprisingly, mutations of individual Hox genes such as HOXA1 can result in specific brain stem abnormalities (OMIM# 601536) (174). It is critical to note that while the Hox genes establish the initial basic patterning within the hindbrain, a network of transcription factors is required to define individual cell types (329).

**15.9.4.3 Cerebellum.** The adult cerebellum is three-layered structure comprising the molecular layer, Purkinje cell layer (PCL), and granule cell (i.e. granular) layer. (See Figure 15-32 for details.) It is derived from rhombomere 1 (r1 in Figure 15-30) by signals produced by the isthmus organizer at the midbrain–hindbrain junction (175). Purkinje cells are produced within the ventricular zone,

**FIGURE 15-30** Early embryonic brain development. The three primary brain vesicles: prosencephalon, mesencephalon, and rhombencephalon. (A) Shows rhombomeres (r) and where specific CNs will exit; “I” is the isthmus at the mesencephalon–rhombencephalon border. Note that the rhombomeres are only structurally visible temporarily, but within them gene expression and the cells they produce have long-lasting effects. (B) Morphological appearance of illustrations in (A). Note the presence of neuromeres corresponding to rhombomeres. The primary brain vesicles develop into five secondary vesicles: the diencephalon and telencephalon (from the prosencephalon), the enlarged mesencephalon, and the metencephalon and myelencephalon (from the rhombencephalon). The cerebral hemispheres appear and undergo rapid expansion. (D) Morphological appearance of illustration in (C). Note the neuromeres are no longer present, but functional segmentation of function has already occurred. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen’s Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

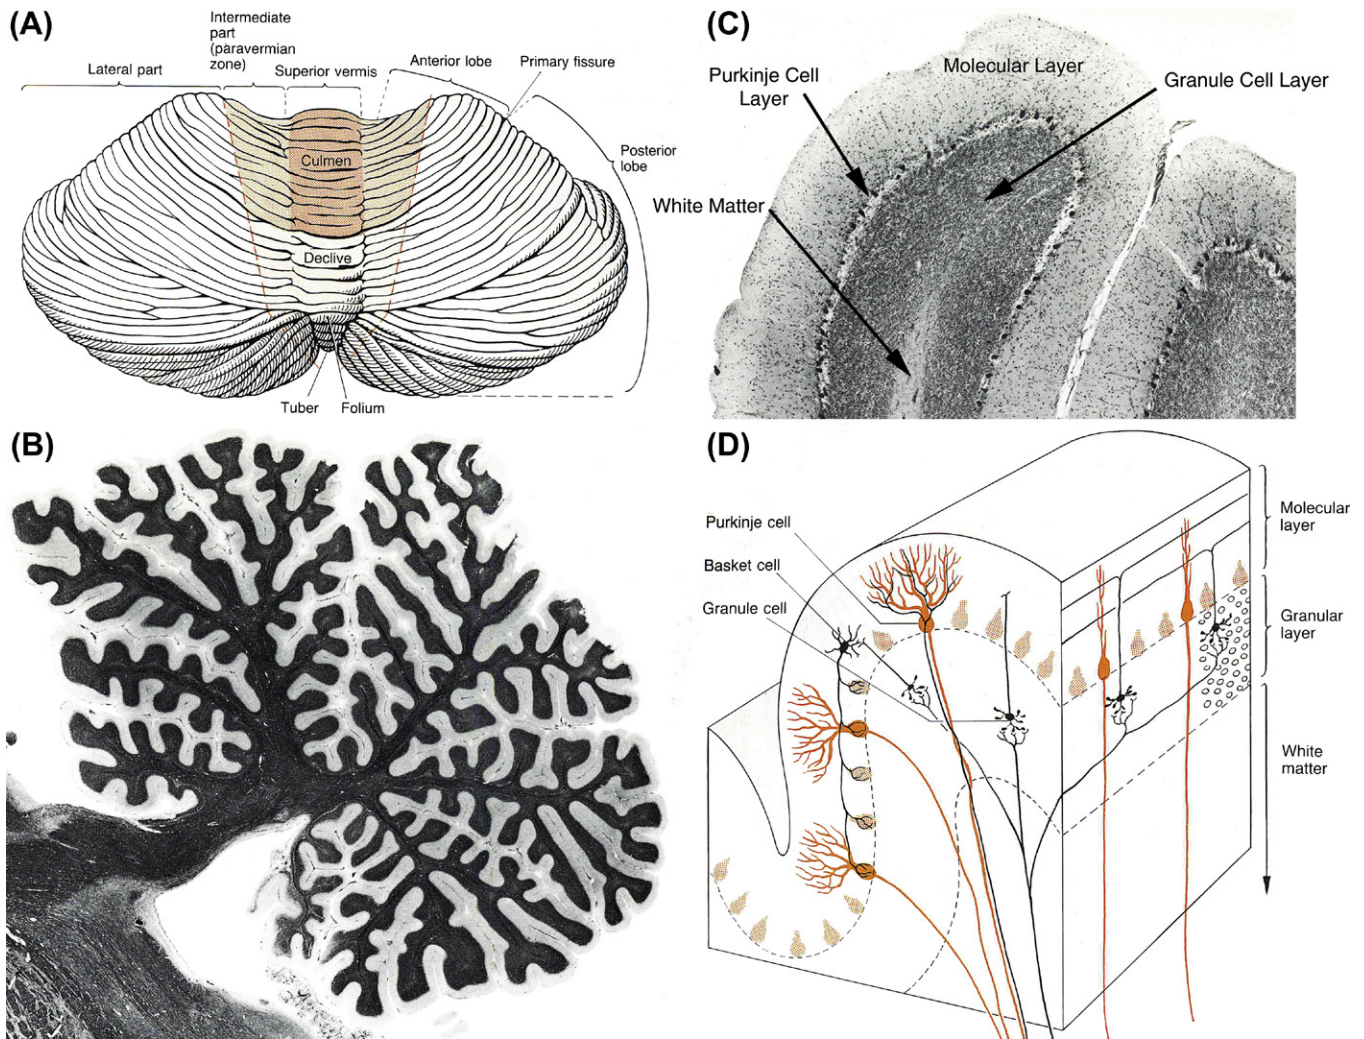

**FIGURE 15-31** Hindbrain and Hox gene expression. Illustration of segmental but overlapping Hox gene expression in the vertebrate (chick) hindbrain along with individual motor CN nuclei (prefixed by “m”) on the right and sensory CN nuclei (prefixed by “g”) on the left emerging from their respective rhombomeres (prefixed by “r”); “ov”—optic vesicle. Also shown are the projections of the motor CNs V, VII, and IX into the first, second, and third pharyngeal arches (b1, b2, and b3), respectively; CN X (vagus nerve) innervates a larger segment of the body. The neural crest derivatives (represented by green arrows) migrate and incorporate into specific pharyngeal arches. (Kiecker, C.; Lumsden, A. *Compartments and their Boundaries in Vertebrate Brain Development*. Nat. Rev. Neurosci. 2005, 6 (7), 553–564.)

likely in the fifth and sixth weeks of gestation. During development, r1 and the plane of the Purkinje cells that derive from it appear to turn 90° (Figure 15-33) (176). Granule cells are derived from the dorsal region known as the rhombic lip, grow over the top of the primordial cerebellum and proliferate through the first postnatal year in humans. Granule cell proliferation is driven by SHH derived from Purkinje cells and is required for the cerebellum to achieve its typical folia growth pattern. Interestingly, as discussed in the section on hedgehog signaling pathway, activating mutations in *PTCH1*, which encodes the receptor for the active hedgehog molecule HH-N, may result in medulloblastomas (178). The genetics of cerebellar development was recently reviewed by White and Stillitoe (179).

Studies of genetic conditions in both animal models and humans have provided specific insights into aspects

of cerebellar development and provided a basis to categorize cerebellar malformation diseases (180). Abnormal migration of Purkinje cells from the ventricular zone to the more dorsal regions disrupts the typical Purkinje cell monolayer and prevents SHH delivery to granule cells for proper proliferation (164,175,176). Mutations in the *reelin* gene (*RELN*), its receptors, or downstream signaling molecules can result in Purkinje cell migration phenotypes such as lissencephaly (OMIM# 257320) or cerebellar ataxia, mental retardation, and dysequilibrium syndrome (OMIM# 224050) (181–187). Mutations that induce the death of Purkinje cells produce a proportional loss of granule cells (188) not only due to the lack of Purkinje cell-produced SHH required for granule cell proliferation but because granule cells require synaptic connections to Purkinje cells for survival. Of note, the midline cerebellum (vermis) during development appears

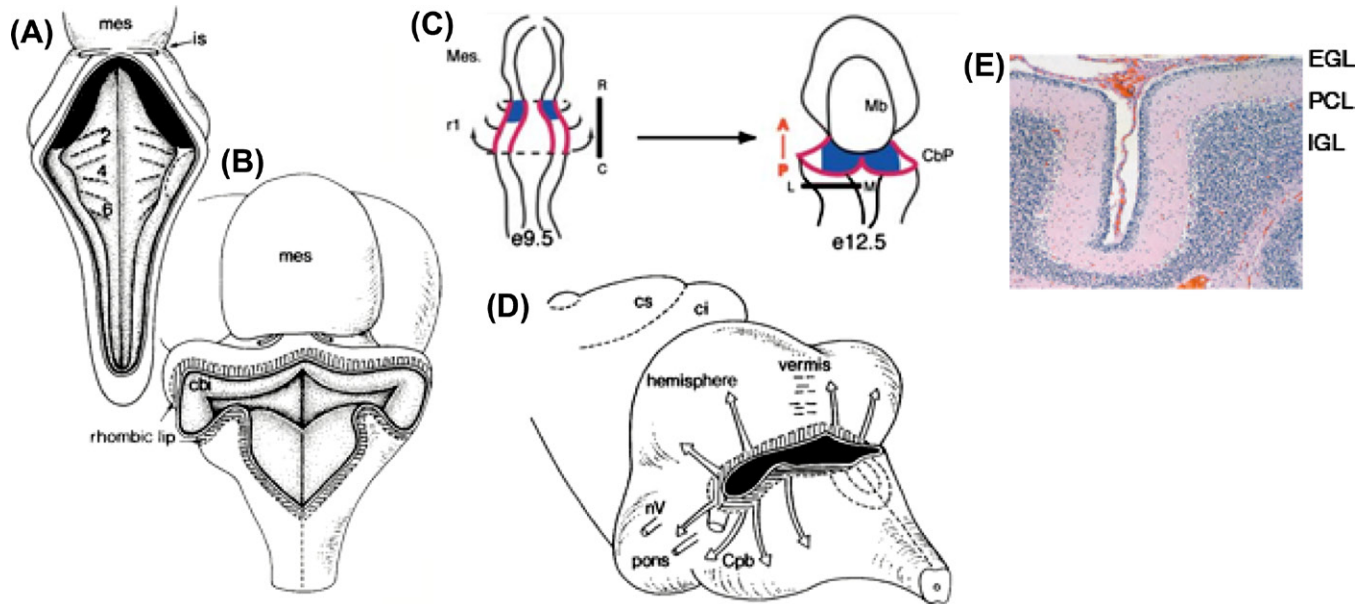

**FIGURE 15-32** (A) A schematic of the human cerebellum as looking at the back of the brain. In the horizontal plane, the cerebellum is divided into the vermis at midline, the lateral lobes more laterally and the paravermian region in between. The midline structures are more critical for control of the axial body and the lateral lobes control the limbs. (B) A sagittal section from the lateral lobes of the cerebellum. The darkly stained areas are both the cell-dense granular layer and the white matter tracts. The molecular layer is the light gray area on the surface of the cerebellum. (C) Higher resolution of individual folia with a cell body stain. The molecular layer contains the unmyelinated axons of the granule cells known as parallel fibers as well as Purkinje cell dendrites that parallel fibers synapse upon. Under the molecular layer is the monolayer of Purkinje cells (large cell bodies). (D) A schematic showing the axis of the Purkinje cell dendrites and the other layers of the cerebellum. (DeArmond, S. J.; Fusco, M. M.; Dewey, M. M. *Structure of the Human Brain, a Photographic Atlas*. Oxford University Press: New York, 1974; Duus, P. *Topical Diagnosis in Neurology*, 3rd ed., Thieme: New York, 1998.)

smaller in size than other regions of the cerebellum (Figure 15-33) but it eventually becomes prominent (Figure 15-32). It has been speculated that either Purkinje cells must migrate more medially or midline Purkinje cells proliferate more to account for the prominence of the vermis. Regardless of the mechanism, vermal hypoplasia with relative sparing of cerebellar hemispheres is found in multiple syndromes including Joubert syndrome (OMIM# 213300) and Dandy-Walker syndrome (OMIM# 220200). General cerebellar hypoplasia is a common feature of many syndromes as well (OMIM# 300486, 300749, 607596, 277470, 604382, 601427). Since granule cell proliferation and cerebellar development continue through the first years of life, it is sometimes difficult to determine if a small cerebellum is due

to developmental abnormalities or from degeneration after normal development of the cerebellum has been completed.

**15.9.4.4 Forebrain.** The forebrain is induced by a complex interaction of multiple factors (189–192). The anterior border of the neuroectoderm and ectoderm, termed the anterior neural ridge (ANR), secretes multiple FGFs, with FGF8 being the best studied (Figure 15-34). These factors induce expression of SHH (see Section 15.8.1) from the non-neuronal axial midline structures and the prechordal plate (ventral to the neuroectoderm). In mice, Shh is required to induce ventral forebrain components and helps to establish the expression of key transcription factors (193–195). Disruption of SHH or many of the downstream SHH signaling molecules result in

**FIGURE 15-33** Cerebellar morphogenesis. (A) The cerebellum is derived from r1 (shown in black). Also shown are the mesencephalon (mes), isthmus (is), and r2, r4 and r6. Note the V-shaped primordial cerebellum. (B) The cerebellum (cb) is a horizontally oriented structure by about 13 weeks gestation. (C) Fate mapping studies show that r1 rotates 90° on its axis with the lateral portions moving more than medial portions (blue engrailed 2 transcription factors as a marker). (D) The rhombic lip produces multiple cell types including cerebellar granule cells, several pontine nuclei and the inferior olive. The granule cells migrate over the surface of the primordial cerebellum (arrows) while the other cell types migrate to their proper locations. (E) Section from postnatal human cerebellum. Granule cells proliferate in the external granule cell layer (EGL). As they stop dividing and differentiate into neurons in the EGL, granule cells extend axons to synapse with Purkinje cell dendrites. Granule cell bodies migrate through the molecular layer and PCL into the internal granule cell layer (IGL). (ten Donkelaar, H. J.; Lammens, M.; Wesseling, P.; Thijssen, H. O.; Renier, W. O. *Development and developmental disorders of the human cerebellum*. J. Neurol. 2003, 250 (9), 1025–1036; Sgaier, S. K.; Millet, S.; Villanueva, M. P.; Berenshteyn, F.; Song, C.; Joyner, A. L. *Morphogenetic and Cellular Movements that Shape the Mouse Cerebellum; Insights from Genetic Fate Mapping*. Neuron 2005, 45 (1), 27–40; Prayson, R. A., *Neuropathology*; Elsevier: Philadelphia, PA, 2005.)

holoprosencephaly (192). Holoprosencephaly is a failure of forebrain induction that results in incomplete separation of the forebrain with variable severity and may be associated with multiple craniofacial abnormalities, most dramatically cyclopia. It can be caused by both genetic and environmental factors that likely reflect multiple pathways associated with forebrain development (192,196).

The cerebral cortex has a highly ordered structure (see Figure 15-35, adult). A small column of cells in cerebral cortex is thought to form a functional unit. The cerebral cortex has two major classes of neurons, named after their predominate neurotransmitters. Glutamatergic neurons (glutamate as the neurotransmitter) are excitatory and many project long distances whereas GABAergic (GABA as the neurotransmitter) neurons are inhibitory and project locally. The cerebral cortical glutamatergic neurons are all produced within the ventricular region of the cerebral cortex. However, in mice, cerebral cortical GABAergic neurons migrate tangentially from the ganglionic eminences (future basal ganglia) (Figure 15-35) (197). In contrast, human GABAergic neurons of the cerebral cortex are derived from both the ganglionic eminences and the cerebral cortex (198,199).

Our understanding of the developing brain is generally based on animals model, rodents being the most

studied. However, the rodent cerebral cortex lacks gyri and is much smaller than other mammals. It is increasingly clear that there appears to be critical differences between mouse and human development and some of these differences will be illustrated below. The cerebral cortex, like the rest of the neural axis, starts as a single layer of pseudostratified epithelium (Figure 15-35, panel 1). Initially, cells proliferate symmetrically with every cell division producing two additional progenitors, increasing the number of cells exponentially. The nuclei move up and down within the pseudostratified epithelium replicating their DNA toward the pial surface and mitosis occurring at the ventricular surface (200). The preplate contains the first neurons of the cerebral cortex and lies between the neuroepithelium (ventricular zone) and the pial surface (Figure 15-35, panel 2) (199). Interestingly, preplate cells are critical for development but later die or play little to no role in the function of the mature cerebral cortex. The Cajal–Retzius cells of the preplate express a large extracellular protein, reelin (encoded by *RELN*), that is critical for proper neuronal migration, the loss of which can result in a form of lissencephaly with microcephaly and thickened cortex (OMIM# 257320) (181,185); these cells subsequently form the marginal zone (MZ). Subplate cells play a role in axonal guidance (201). Within the ventricular zone,

**FIGURE 15-34** There is a complex balance between factors that induce the forebrain and cause specific regions to develop properly. Fgf8 and other FGF proteins are expressed by the ANR. FGF causes the induction of Shh in the prechordal floor plate that later induces Shh in the ventral forebrain. SHH is required for the continued expression of FGFs from the ANR. In the dorsal forebrain, Wnts and Bmps induce dorsal regionalization in a structure called the cortical hem. The anti-hem is a region near the border of the lateral cerebral cortex and the lateral ganglion eminence (border between dorsal and ventral telencephalon). This region expresses several proteins including Tgfa, Fgf7, and Sfrp2 that are functionally antagonistic to the hem-expressed proteins. In mice, the balance of secreted factors leads to the expression gradients that appear to be required for regionalization of functional domains of the cerebral cortex. (O’Leary, D. D.; Sahara, S. *Genetic Regulation of a Realization of the Neocortex*. *Curr. Opin. Neurobiol.* 2008, 18 (1), 90–100.)

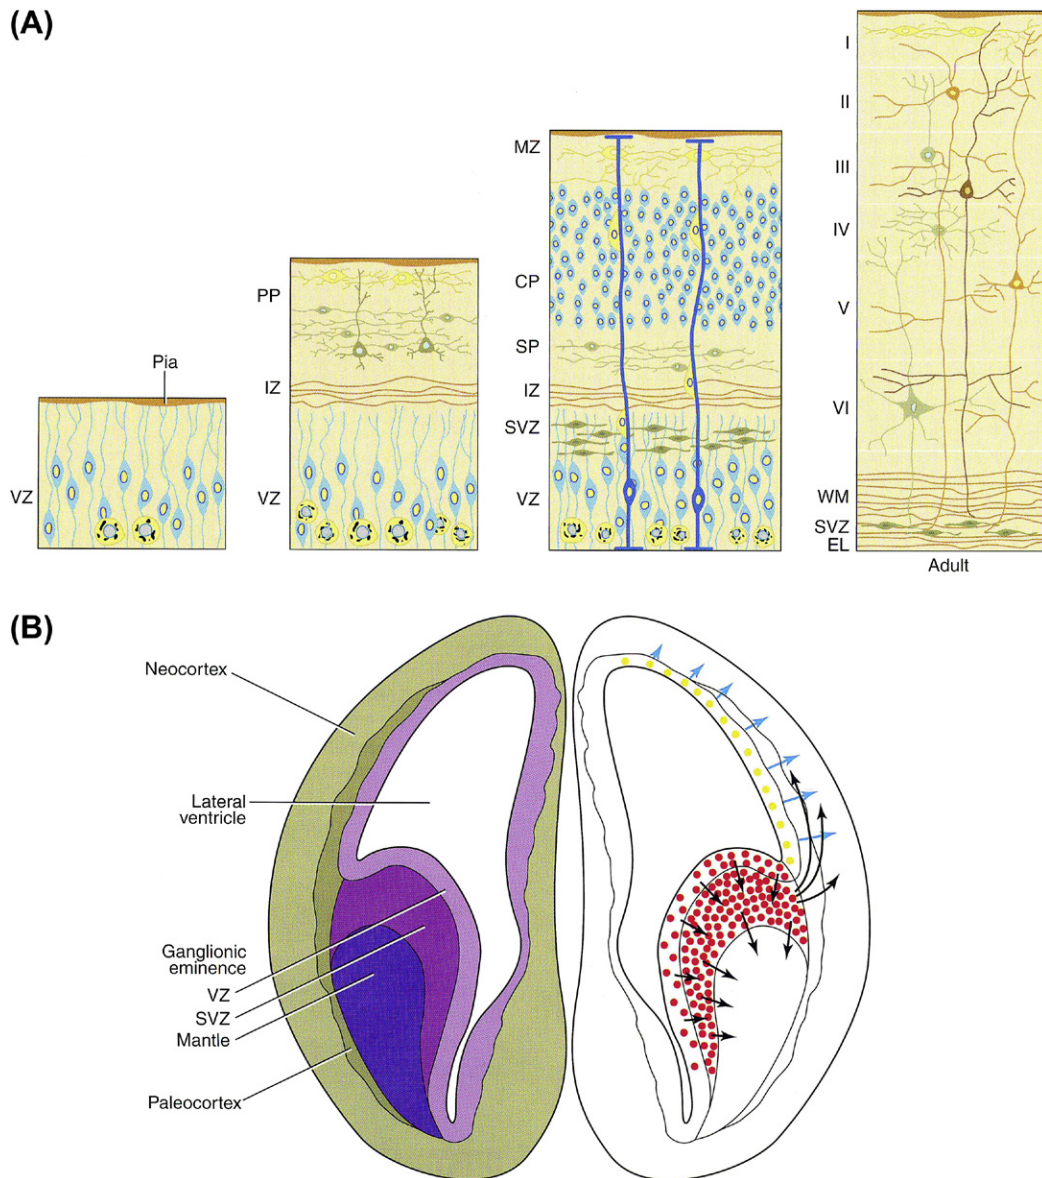

after a period of symmetric cell division and exponential increase in the number of cells, some cells will begin to differentiate into neurons. While many cells continue to expand the ventricular zone by dividing symmetrically, some divide asymmetrically to produce one progenitor and one differentiated neuron (202–204). Cells that differentiate into neurons migrate away from the ventricular zone and split the preplate into the MZ (future layer I) that contains the Cajal–Retzius cells and the subplate with the subplate neurons (Figure 15-35, panel 3). In addition, some neuronally committed cells migrate away from the ventricular surface to form the (inner) subventricular (SV) layer and begin to change their expression profile (205,206). These cells then generally go through one additional round of proliferation to produce differentiated neurons. In addition, it now appears that mammals with gyri and larger brains have additional sources of dividing cells that are uncommon in mice. The outer SV zone appears to have extensive proliferative capacity and is thought to be an important source of cells in mammals with larger brains (207–209) in contrast to the inner SV zone cells that appear to divide only once before terminally differentiating into neurons. After multiple cell symmetric divisions producing more precursors,

outer SV zone cells differentiate, but the extent of their role for producing neurons in gyric mammals remains to be definitively determined (Figure 15-36).

**15.9.4.5 Congenital Structural Brain Malformations.** Microcephaly may be caused by developmental or degenerative genetic diseases, or injuries to the brain from vascular insults, infection, trauma, or other causes. Only developmental microcephalies are addressed in this chapter. Developmental microcephaly has many different genetic etiologies (210–212). Since the cerebral cortex is the largest structure in the human brain, it is almost always affected in these conditions. Microcephaly vera (true microcephaly) is defined as microcephaly in the absence of other neurological findings except intellectual disability. Mutations in eight different genes have been found to be associated with microcephaly vera: *MCPH1* (213), *ASPM* (214), *CDK5RAP2* (215), *CENPJ* (215), *STIL* (216), *WDR62* (217–219), *CEP152* (220), and *CEP63* (221). All of these genes encode proteins associated with the centrosome, but they do not appear to have the same role in centriole duplication or centrosome function (222,223).

Since microcephaly vera has a “small brain” as its only phenotype, it is a useful model for understanding developmental microcephaly (Figure 15-37) (330). Moreover, microcephaly vera is associated with a reasonably normal body size, suggesting that the centrosomal-related mechanism leading to deficient production of neurons is largely brain specific. Some microcephaly vera genes have been shown to increase the amount of asymmetric cell divisions in mouse models within the ventricular zone producing more neurons prematurely as opposed to symmetric cell divisions which produce more precursors (226–228). Excessive asymmetric cell division early in development can result in a deficiency of precursors in late neurogenesis (204). This mechanism may also be responsible for conditions with neuronal migration abnormalities since the centrosome is also important for neuronal migration (229,230). Of note, the effects of mutations in these microcephaly genes on the outer SV zone is unknown since mice, the most common genetic model organism for cerebral cortical development, are largely deficient in this cell type (207–209).

Microcephaly is also associated with abnormalities in DNA repair (231). The phenotypes for these conditions, in addition to microcephaly, include somatic growth retardation (Seckel syndrome 1 and 2: OMIM# 210600, 606744) (232), somatic growth retardation and immunodeficiency (Nijmegen breakage syndrome: OMIM# 251260 (233–235) and LIG4 syndrome: OMIM# 606593 (236)), and microcephaly with seizures (early infantile epileptic encephalopathy-10: OMIM# 613402) (237). Studies in mouse models suggest that microcephaly in these syndromes is likely due to neuronal progenitors cell death shortly after differentiation (231,238–240). The reasons for developing neurons to be so sensitive to abnormalities in DNA repair remains a mystery.

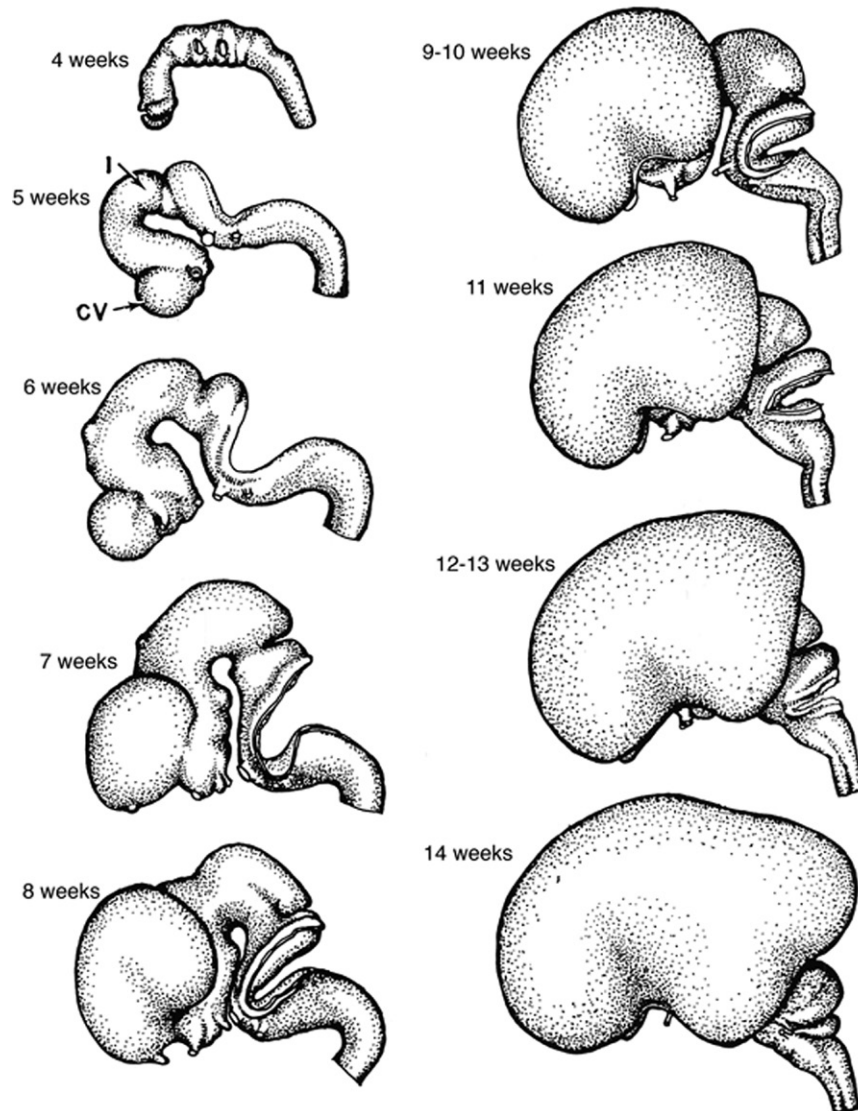

**FIGURE 15-35** (A) Different stages of cerebral cortical development. *Panel 1:* Pseudostratified neuroepithelium with cells having connections at the pial and ventricular surfaces; this structure can be considered the ventricular zone (VZ). *Panel 2:* Preplate (PP) is formed from both Cajal–Retzius and subplate neurons. Intermediate zone (IZ) is in between preplate and ventricular zone. *Panel 3:* The SV zone contains two different types of precursors, cells with either limited (inner SV zone cells) or extensive (outer SV zone cells) proliferation capacity. Differentiated neurons form the CP, from which the future neurons of the cerebral cortex arise, by splitting the preplate into the MZ containing Cajal–Retzius cells and the subplate (SP). Most neurons migrating from the ventricular region to the CP use radial glial (long dark blue cells) processes, many of which are processes of ventricular zone cells connected to the pial surface. *Panel 4 (Adult):* The layers of the cerebral cortex are distinguished by the glutamatergic neurons. The top layer closest to the meninges or pia surface (layer I) is cell sparse and includes dendrites and axons. Layers II and III contain small- to medium-sized neurons that generally send axons to different parts of the cerebral cortex. Layer IV receives axonal projections from the thalamus and send axons to other layers generally within its own functional unit. Layer V consists of very large neurons and projects to distant structures such as the brain stem and the spinal cord while layer VI projects to the thalamus. Below layer VI are myelinated white matter tracts containing axons projecting both in and out cerebral cortex as well as intracortical projections. (B) Diagram of coronal section of embryonic mammalian forebrain during development. Glutamatergic neurons of the cerebral cortex are derived from cerebral cortical ventricular and migrate radially (light blue arrows). Many GABAergic neurons are derived from the ganglionic eminences and migrate tangentially into the cerebral cortex. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

As stated above, glutamatergic neurons are born within both the ventricular and the SV zones of the developing cerebral cortex while GABAergic neurons migrate in from the ganglionic eminences or from the SV zone. This illustrates that the final destination of differentiated

neurons is not generally where they proliferate and begin their differentiation, so neuronal migration is an important process in brain development. There are two broad categories of neuronal migration, radial and tangential. Radial migration is in the direction of orientation of the

**FIGURE 15-36** Drawings of human brain development from 4 weeks to 14 weeks gestation ("I" is the isthmus and "CV" is the cerebral vesicle). Note that the cerebral vesicle starts at the most rostral end of the neural axis. However, it grows and eventually covers the more caudal segments including the diencephalon (thalamus and hypothalamus), mesencephalon (midbrain), and occipital regions, and it eventually rests above of the hindbrain. The images are not scaled to each other (160). (F. Hochstetter, *Beitrage Zur Entwicklungsgeschichte Des Menschlichen Gehirns I*, Deuticke, Vienna, 1919.)

undifferentiated precursors and often uses processes of those precursors (radial glia, long blue cells in panel 3 [Figure 15-35A](#) and light blue arrows in [Figure 15-35B](#)) as a substrate to "climb" on ([241,242](#)); tangential migration occurs as neurons migrate perpendicular to the plane of the progenitors ([Figure 15-35B](#): black arrows into developing neocortex) ([197](#)). Differentiating glutamatergic neurons migrate from where they were "born," which is close to the ventricular zone, toward the pial surface, arresting in the cortical plate (CP) forming the future neurons of the cerebral cortex ([243,244](#)). As neurons continue to differentiate, newly "born" neurons migrate away from the ventricular zone regions past all previously born and reside below layer I ([Figure 15-38](#)). This means that cerebral cortex is "born" inside out,

with the deepest neurons of layer VI being born first and the latest born neurons in Layer II.

There are many different recognizable abnormalities in neuronal migration that are frequently associated with epilepsy ([246,247](#)). These abnormalities are seen on neuroimaging as gray matter (neurons) where they do not belong or abnormalities in the structure of the cortex. Neuronal migration abnormalities can occur because of genetic or environmental insults during critical aspects of neuronal migration ([248](#)). Neurons can be found at the ventricular surface where they are born in the form of periventricular heterotopia (OMIM# [300049](#), [608097](#)) ([249,250](#)). Periventricular heterotopia is caused by abnormalities in the initiation of neuronal migration, which may be due to a disruption of the ventricular surface

**FIGURE 15-37** Pre- and postnatal brain growth from about 13 weeks post-fertilization to 60 months after being born at full term (prenatal ages in red and postnatal ages in black). Note that while the microcephaly vera phenotype is very likely to be secondary to deficiencies in proliferation of neurons of the cerebral cortex, these neurons have completed proliferation at the start of the curve above (Table 15-7). Therefore, all the brain growth that is seen on this curve is due to other processes such as glia proliferation, synapse formation, myelination, etc. However, these processes are dependent on the number of neurons generated by 18 weeks gestation. The growth curve is a mathematic composite of fetal (224) and childhood (225) data and is intended for illustrative purposes, not for clinical use.

**FIGURE 15-38** Detailed schematic of neuronal migration: Nuclei move up and down within the ventricular zone with precursors (radial glial cells, light green). Asymmetric cell division occurs when a differentiated neuron (dark green cell) initiates migration to CP utilizing radial glia. Asymmetric cell division occurs again and a white cell is produced that moves to the SV zone and assumes a different morphology before dividing again. The dark green cell releases itself from the radial glial process after receiving the putative stop signal at or near the pial surface. (Kriegstein, A. R.; Noctor, S. C. *Patterns of Neuronal Migration in the Embryonic Cortex*. Trends Neurosci 2004, 27 (7), 392–399.)

close to where neuroblasts proliferate (251). A disruption in neuronal migration can also result in lissencephaly (smooth brain) in which neurons lack their normal organization within the cerebral cortex (185,252–257). An interesting example is *DCX*, an X-linked gene that causes lissencephaly in males and a double cortex (i.e. a normally formed cortex at the proper location and a subcortical band of abnormally migrated neurons) in females (OMIM# 300067) (253–255). This gender difference in phenotype arose because disruption of the only copy of

their *DCX* gene on their single X chromosome in males causes all neurons to migrate improperly, while random X-inactivation in females results in properly migrating neurons when the X chromosome carrying the mutant gene is inactivated and improper migration only if the non-mutant X chromosome is inactivated. Many genes associated with lissencephaly syndromes encode for proteins involved in centrosomal or microtubule activity, and as discussed above, are often associated with microcephaly as well (258,259). Cobblestone lissencephaly, that is, a smooth brain with some bumps upon the surface, is due to over-migration of neurons past their normal arresting point and onto the pial surface of the cerebral cortex (259). This is caused by mutations in genes that result in glycosylation defects (260,261). In addition to cobblestone lissencephaly, these mutations also result in congenital muscular dystrophy and various structural ophthalmologic abnormalities. This group of conditions is now known as “congenital muscular dystrophy–dystroglycanopathy with brain and eye anomalies” (OMIM# 236670, 613150, 253280, 253800, 613153, 613154, 614643). Another recognizable pattern of brain malformation is polymicrogyria, which can be due to a variety of genetic and environmental etiologies (262). One genetic form of polymicrogyria that is associated with an over-migration phenomenon resulting in a cobblestone-like lissencephaly in a mouse model is bilateral frontoparietal polymicrogyria (OMIM# 606854) due to mutations in *GPR56* (263). Since schizencephaly is often associated with polymicrogyria, it is possible that these two phenomena share similar pathogenesis, but schizencephaly is also associated with holoprosencephaly (264).

**15.9.4.6 Development of Synapses and Axonal Path Finding.** The remaining aspects of neuronal development will only be addressed in a cursory manner. This is not because they are not important, but because their disruption is often only associated with intellectual disability or other cognitive dysfunction, which makes clinical classification and therefore genetic characterization challenging. Furthermore, establishing the cellular mechanism of cognitive dysfunction in animal models is generally more difficult for intellectual than it is for structural abnormalities because structural pathophysiological correlates between human and mouse brains often appear more convincing than behavioral correlates of cognitive dysfunction. Shortly after differentiation and sometime during migration, neurons extend their axons to reach their desired target. There are many different cues that each neuron must take to find their proper target (159). Once axons reach their targets, synapses are formed. There is considerable communication between pre- and post-synaptic structures that strengthen or weaken synapses based on the firing characteristics of each cell and synapse type. Ion channels determine the electrical characteristics of a neuron. Most neurons are also thought to require a functional connection with an appropriate target from which they will receive trophic factors

that are required for their survival, as seen in granule cells and Purkinje cells in the cerebellum. This has been hypothesized to foster a Darwinian-like competition between neurons for the best connections. Neurons that are unable to make proper connections to targets during development due to missing targeting cues, less efficient connections with targets, or lack of targets die through programmed cell death (265). Many synapses are made early in childhood; however, these synapses continue to be created, lost, strengthened, or weakened overtime as more experience is accumulated (all these processes are reviewed in more detail in Purves et al. 2012 (159)).

Axonal path finding, neuronal firing characteristics, and synaptic plasticity are thought to be associated with various cognitive defects. However, due to the dearth of definitive genetic evidence for these mechanisms in conditions such as autism or psychiatric illnesses and the difficulties in modeling human cognitive impairments in animal models, these hypotheses are generally difficult to prove conclusively. However, some epilepsy syndromes have been found to be associated with mutations in a single gene (266–269). Since ion channel genes regulate action potentials, it should not be surprising that epilepsy is frequently associated with mutations in these genes, although mutations in genes that control the formation of brain structures often result in epilepsy as well (269). An example of a gene associated with intellectual disability and neuronal path finding abnormalities is MASA (mental retardation, aphasia, shuffling gait, and adducted thumbs) syndrome, also known as spastic paraplegia-1 due to mutations in an X-linked gene, *L1CAM* (OMIM# 303350) (270). This is allelic with X-linked hydrocephalus (OMIM# 307000) and the acronym CRASH (corpus callosum hypoplasia, retardation, adducted thumbs, spastic paraplegia, and hydrocephalus) syndrome describes the range of anomalies that can be seen in individuals with *L1CAM* mutations. The identification of the underlying pathophysiology in cognitive disorders can be critical and potentially fruitful. For example, Fragile X syndrome (OMIM# 300624) is a syndromic form of intellectual disability that is not associated with gross structural brain abnormalities but has been shown to have synaptic changes (271). This has led to the investigation of potential therapeutic interventions based on our knowledge of its neuropathophysiology (272). There is hope that as we learn more about the genetic etiology and developmental pathways in various neurodevelopmental disorders, we will be able to develop targeted therapies for these disorders.

### 15.9.5 Limbs

Higher vertebrates have two sets of distinguishable paired limbs: forelimbs and hindlimbs. Although the precise form of the limbs varies between species, they share a common morphologic pattern (273,274). Each limb is composed of three major components, from proximal to

distal: the stylopod, zeugopod, and autopod. In humans, the stylopod is a single proximal long bone (the humerus in the arm and the femur in the leg), the zeugopod is a middle pair of long bones (ulna and radius in the arm, tibia and fibula in the leg), and the autopod are the carpal (hand) or tarsal (foot) bones, with the phalanges of the digits being most distal. The ordered development of the limb must produce correct orientation in three planes: proximal–distal (shoulder to fingers), anterior–posterior (thumb to little finger), and dorsal–ventral (back of hand to palm). How these axes are established and maintained depends on the precise coordination of multiple signaling molecules and transcription factors. The lateral plate mesoderm gives rise to the bone, cartilage, and tendons while the somitic mesoderm gives rise to the muscle and neurovascular bundle (nerve and blood vessels) of the vertebrate limb.

Initiation of the outgrowth of limb buds involves members of the FGF family. *Fgf10* is expressed in the lateral plate mesoderm prior to the onset of limb budding. As the bud arises, an apical ridge that expresses *Fgf8* forms in the ectoderm overlying the bud (the apical ectodermal ridge (AER)) (275–277). The forelimb and hindlimb are morphologically quite distinct. The signals specifying whether a forelimb or a hindlimb forms and the position of the limb relative to the rest of the body appear to correlate with the expression of the genes in the Hox9 paralogous group (278). In addition, the T-box (*Tbx*) genes, which encode another family of transcription factors, are differentially regulated in forelimb versus hindlimb (279–282). *Tbx4* is expressed in the hindlimb, while *Tbx5* is expressed in the forelimb. *Pitx1*, which can induce *Tbx4* expression, encodes a bicoid-like transcription factor and is also expressed in the early hindlimb. Expression of *Pitx1* ectopically in the forelimb can induce hindlimb identity while the *Pitx1* knockout mouse has abnormalities of the hindlimb (283–285).

**15.9.5.1 Longitudinal Growth of the Limb: The Proximal–Distal Axis.** The AER, a specialized region of ectoderm, is essential for the outgrowth of the limb from the bud. It forms at the tip of the limb bud along its dorsal–ventral boundary. The position and maintenance of the AER appear to depend on signals from the underlying mesenchyme. The AER itself is also the source of secreted factors that allow for longitudinal outgrowth of the limb. Excision of the AER causes the limb to stop growing distally, resulting in a truncation defect (i.e. loss of distal structures) (286,287). The structures that are lost depend on the timing of the removal of the AER. If the AER is removed early, the limb is severely truncated, while later removal results in loss only of more distal structures. At least three FGFs are known to be expressed in the AER: *FGF4* posteriorly, and *FGF2* and *FGF8* throughout the ridge (288–291). The progress zone is a region of rapidly proliferating undifferentiated mesenchyme that lies beneath the AER. This region specifies the proximal–distal axis in the developing limb.

Cells in the AER differentiate into their final cell type while cells in the ZPA are kept undifferentiated.

The exact mechanisms through which the proximal–distal axis in the limbs is established have remained controversial and many models have been suggested (292). In the “Progress Zone Model,” the proximal–distal identity of the bone is determined by the amount of time that a given cell has spent in the progress zone under the influence of permissive FGF (293,294). If a cell has spent only a short amount of time in the zone, a proximal bone (e.g. humerus) will form; conversely, cells that exit from the zone last and have spent the most time in the zone will form distal elements (e.g. distal phalanges). This model assumes that cells somehow measure the time spent in the progress zone and thus obtain their positional identity, but this model has been challenged (295). A second model is the “Early Specification Model” in which the expression of genes that regulate limb specification early in development result in the formation of “small stripes across the early limb bud” (292), each with its unique specific limb identity. With proliferation, these stripes would subsequently increase in size and form the appropriate limb component that had been specified (294). However, neither of these models is supported by experimental evidence and many other models have been suggested, one of which is a “dynamic expression” approach that attempts to integrate the various signals that arise from the flank, the AER, and the developing limb itself (292).

In chick models of limb development, it has been shown that dissociated cells from the distal limb bud that are exposed to RA can be “reprogrammed” to develop proximal limb elements, that is, adopt a “proximal identity” (296). Moreover, this proximal re-specification can be inhibited by RA antagonists but can be promoted by FGF receptor antagonists (297), which suggests that RA and FGF have diametrically opposite effects on proximal specification in the developing limb. However, some recent studies have casted doubts on the role of RA in proximal–distal limb patterning and some authors have suggested that RA facilitates “remote signaling” but is not required for the local patterning of the limb bud (297).

FGFs from the AER regulate the expression of many genes involved in the outgrowth of the developing limb bud. We will discuss the functions of four of these genes as examples of the genetic control of limb development: *MEIS1*, *HOXA11*, and *HOXA13* in the stylopod, zeugopod, and autopod, respectively, and *AP2* in the undifferentiated zone that is responsive to AER/FGF signaling. The spatial and temporal expression of these genes is illustrated in Figure 15-39.

The marker for stylopod (*MEIS1*) and the marker for the undifferentiated zone (*AP2*) are initially co-expressed in the earliest developing limb bud, which in the chick would be at developmental stage 17. It is believed that *MEIS1* expression is induced by RA signaling from the

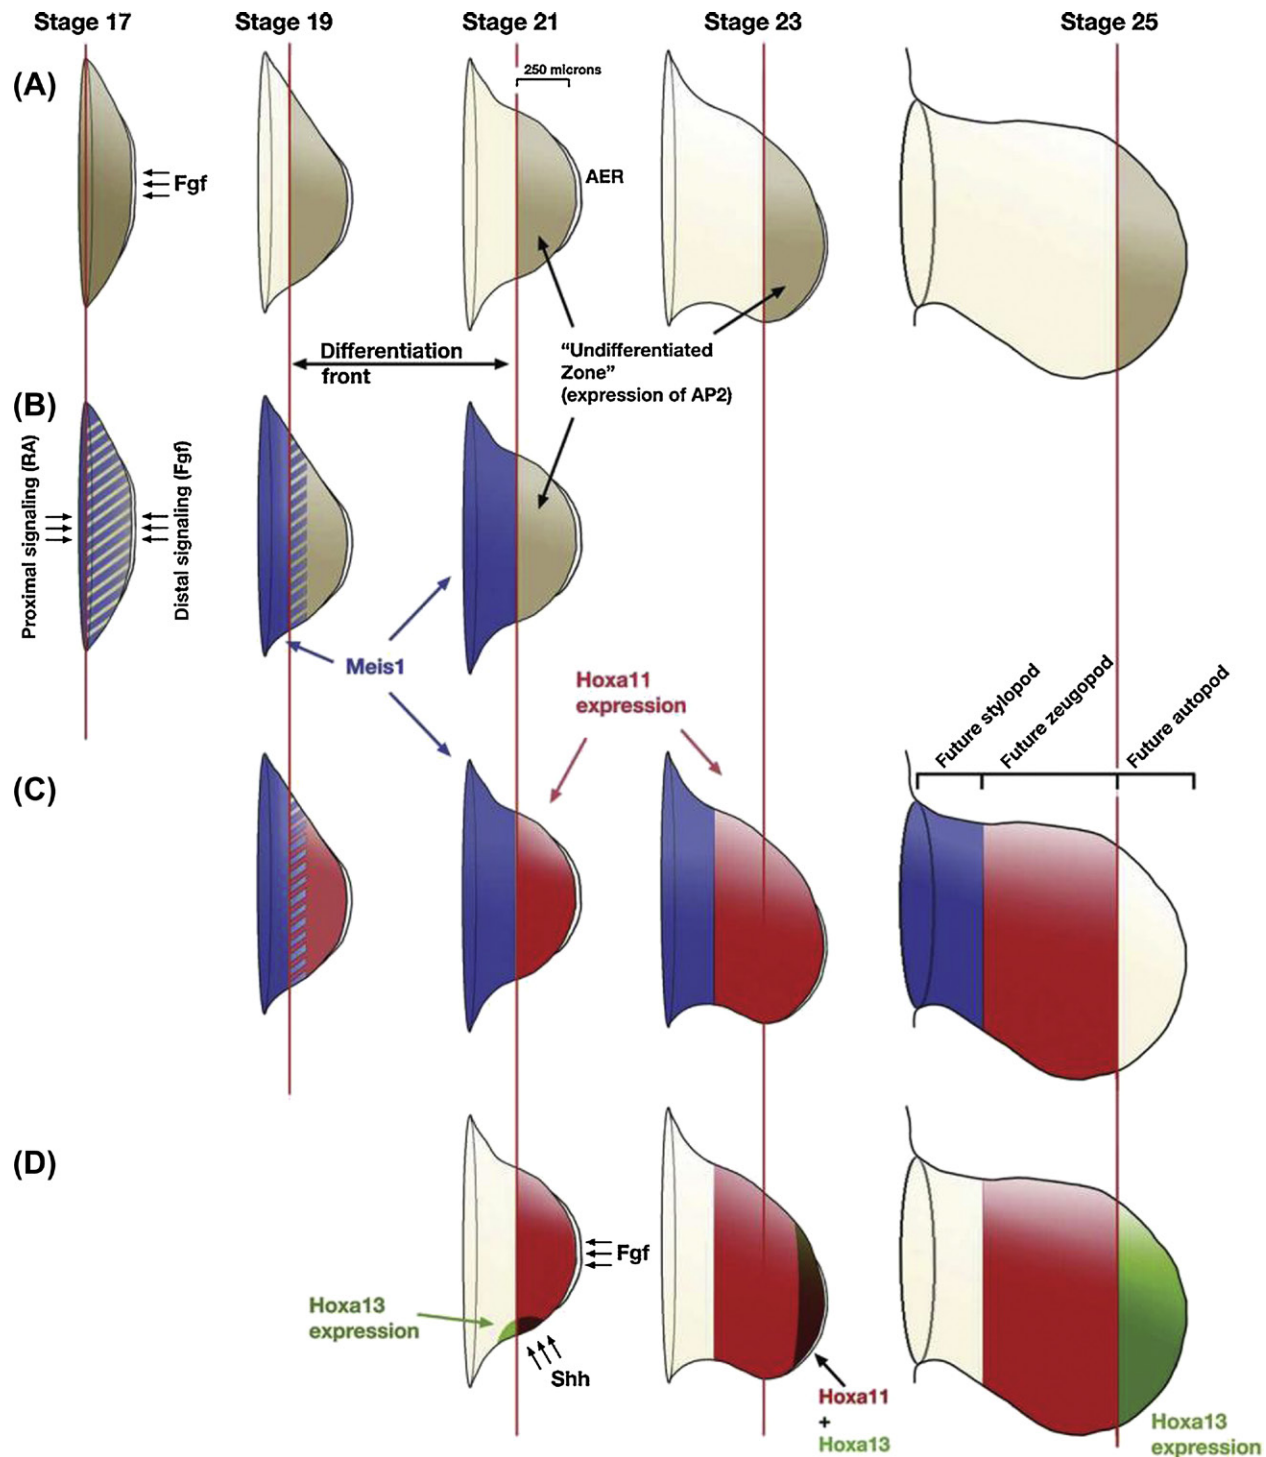

flank (i.e. proximal signaling) while *AP2* expression is induced by FGF signaling from the AER (i.e. distal signaling). Due to the tiny size of the limb bud at this early stage of development, it is conceivable that all the cells in the limb bud are exposed to both the proximal and the distal signals. As the limb bud increases in size, expression of *MEIS1* becomes restricted to the proximal region while expression of *AP2* becomes restricted to the most distal region of the limb bud. Expression of *HOXA11* begins in the chick embryo at developmental stage 19 as the regions that express *MEIS1* and *AP2* become increasingly distinct; *HOXA11* begins to fill the void created by this separation even before the *MEIS1* and *AP2*-expressing regions are completely distinct. Subsequently, *HOXA13* is expressed in the region distal to the *HOXA11*-expressing region. Although there is initially overlap between the adjacent regions, these regions are distinct by the time of differentiation (292).

Differentiation of the different regions of the limb bud to their corresponding musculoskeletal structure is partly dependent on the proper spatial and temporal expression of the *HOXD* cluster of genes, particularly *HOXD9* to *HOXD13*, as shown in Figures 15-40 and 15-41.

The specification of forelimbs versus hindlimbs is determined partly by the expression of specific T-box (*Tbx*) genes, which encode transcription factors—*TBX4* is expressed only in the hindlimbs while *TBX5* is expressed only in the forelimbs (298). As such, mutations in *TBX4* result in the small patella syndrome (OMIM# 147891), which is associated with hypoplastic or absent patella as well as structural pelvic abnormalities and mild anomalies in the feet (increased gap between the first and second toes). In contrast, mutations in *TBX5* result in Holt–Oram syndrome (OMIM# 142900), which is associated with structural heart defects (usually atrial or ventricular septal defects), cardiac conduction defects (usually AV blocks), and malformations of the upper limbs.

**15.9.5.2 Dorsal–Ventral Specification.** Signaling by the dorsal and ventral ectoderm of the early limb bud regulates dorsal–ventral axis specification (299). Dorsal identity is controlled at least in part by *Wnt7a*, and null mutations in the mouse result in ventralization of distal dorsal aspects of the limb (300). *Wnt7a* induces expression of *Lmx1* in the underlying mesenchyme. *Lmx1b* mutation results in partial loss of dorsal structures (301). Ectopic expression of either *Wnt7a* or the LIM homeobox gene *Lmx1* in the chick can induce ventral tissues to become dorsal, resulting in a mirror-image dorsal limb (302,303). The homeobox gene *Engrailed-1* (*En1*) appears to be important for ventral specification. Loss of *En1* expression causes dorsal specification of the ventral limb with ventral expansion of the dorsal markers *Wnt7a* and *Lmx1*, resulting in a double dorsal limb (304,305). However, in the *Wnt7a* knockout, *En1* expression is not altered (300). This implies that limb cells have a ventral identity unless signaled by *Wnt7a*

**FIGURE 15-39** (A) Approximate map of the undifferentiated zone in the distal 250  $\mu\text{m}$  of the limb bud (tan) at various stages of limb development in the chick. (B) Comparison of the domains of expression of *MEIS1* (a stylopod marker; blue) and *AP2* (an undifferentiated zone marker; tan) at different stages of limb development. (C) Comparison of the domains of expression of *MEIS1* (a stylopod marker; blue) and *HOXA11* (a zeugopod marker; red) at different stages of limb development. (D) Comparison of the domains of expression of *HOXA11* (a zeugopod marker; red) and *HOXA13* (an autopod marker; green) at different stages of limb development. *HOXA11* and *HOXA13* expression overlap at early stages of their expression (brown). (Tabin, C.; Wolpert, L. Rethinking the Proximodistal Axis of the Vertebrate Limb in the Molecular Era. *Genes. Dev.* 2007, 21 (12), 1433–1442.)

or *Lmx1* to acquire a dorsal fate. *En1* preserves ventral identity by suppression of *Wnt7a* expression in the ectoderm and subsequently *Lmx1* expression is confined to the dorsal limb mesenchyme. In addition, *En1* seems

to play a role in restricting the AER to the apex of the bud (305,306). Haploinsufficiency of *LMX1B* results in nail-patella syndrome (OMIM# 602575), characterized by abnormalities in the nails, knees, elbows, and pelvis

**FIGURE 15-40** Expression of HOXD9 to HOXD13 regulate the development of specific bones in the upper limbs. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

**FIGURE 15-41** Diagram showing the expression of HOXD9 to HOXD13 in the developing limb bud overtime—proximal end on the left and distal end of the limb bud on the right. (Schoenwolf, G. C.; Bleyl, S. B.; Brauer, P. R.; Francis-West, P. H. *Larsen's Human Embryology*, 4th ed., Churchill Livingstone: Philadelphia, 2008.)

(iliac horns). These clinical features are consistent with the findings described above since the nail and patella are dorsal structures in the limbs.

**15.9.5.3 Anterior–Posterior Patterning.** In humans, the anterior digit is the first digit, or thumb, and the posterior digit is the fifth digit. Anterior–posterior patterning

is controlled by the ZPA. The ZPA confers posterior identity on limb mesenchyme cells, with the cells closest to the ZPA acquiring the most posterior fate. Transplantation of an ectopic ZPA to the anterior margin of the chick limb bud results in mirror-image duplication of the digits. That is, the normal 2-3-4 pattern of digits is replaced by a 4-3-2-2-3-4 pattern. This pattern is presumably the result of cells at a greater distance from the ZPA being exposed to a lower concentration of a morphogen than those closer to the ZPA. The concentration of the morphogen reflects the distance from the ZPA. The implication is that the specification of which particular digit will form at a given site is dependent on a certain threshold for activation. This classical model explains why mirror-image duplications would result from application of a second ectopic ZPA, as there would be two sources of the morphogen. This model would also predict that application of an increased amount of the morphogen at a given position would induce more posterior development. When two ZPAs are grafted onto a wing bud, one at the apex and one at the anterior portion, only the more posterior digits are formed (307).

As described earlier, the properties of the ZPA suggest the presence of a morphogen gradient, and the soluble factor SHH has been shown to play a role. The effect of the ZPA in determining digit identity in the chick can be mimicked by the application of Shh (308). Shh signaling is dose dependent, as would be predicted for a morphogen. Chick limbs exposed to beads soaked in high concentrations of Shh specify a more posterior digit, while progressively lower concentrations induce correspondingly more anterior digits. However, in that series of experiments, it was found that no digit was induced for 12–16 h after the initial exposure to SHH, but three wing digits (d2, d3 d4) were subsequently induced over a period of 8 h (309). This led to a revision of the classical model of anterior–posterior patterning known as the promotion-morphogen gradient model in which both the concentration and the duration of exposure to a morphogen are critical for the specification of digits (310). Other models of anterior–posterior patterning (specifically digit determination) that have been proposed based

on mouse and chick models include the temporal-spatial gradient model, which incorporates the cumulative amount of SHH that the target cells are exposed to and the temporal gradient of the exposure; and the biphasic model in which SHH plays an early and “transitory” role in determining digit identities but is required throughout the development of the limb to ensure that there are sufficient “digital precursor cells” (310). The failure to establish digit identity is often associated with oligodactyly (i.e. missing digits). Hence, the generation of digital identity and the expansion of the digital plate are closely related.

Application of RA to the anterior margin can also induce mirror-image duplication and mimic ZPA signaling (311–313). It has subsequently been shown that RA activates Shh (308). Application of RA inhibitors results in loss of Shh expression in the posterior limb bud (314,315). Thus, the anterior-posterior axis patterning effects of RA could be mediated by Shh, and Shh may be the morphogen that specifies position across that axis of the limb. RA can also induce expression of *Hoxb8* in the limb (316), the ectopic expression of which can result in ectopic Shh expression in the mouse (317). *Hoxb8* is normally expressed in the lateral plate mesoderm, with an anterior expression boundary at the posterior region of the forelimb bud in chick and mouse (316–318). Thus, it appears that *Hoxb8* may specify the position of the ZPA in the lateral plate mesoderm. Activation of expression of regulatory genes at the 5' region of the *Hoxa* and *Hoxd* clusters is controlled by patterning cues, and the patterns of expression map out different regions of the limb bud (319). At least 23 different Hox genes are expressed during chick limb development (320). *Hoxa* and *Hoxd* are expressed in both the forelimb and the hindlimb. Expression of the Hox genes is very dynamic.

Maintenance of Shh expression and the ZPA can be regulated by *Fgf4* from the AER (321,322). Shh also maintains *Fgf4* expression in the AER. In this way, proximal-distal patterning and anterior-posterior patterning are linked. Mutant mice null for *Shh* have proximal structures in the limbs but not distal ones, indicating that Shh plays a role in maintaining proximal-distal outgrowth but not in initiating limb growth. Although *Fgf4* can maintain *Shh* expression in the AER, *Fgf4* may not be required as evidenced by a conditional knockout of *Fgf4* that still had *Shh* expression in the AER (323). It is possible that there is functional redundancy between different Fgf family members.

The bone morphogenetic protein-2 gene (*Bmp2*) is expressed in a pattern overlapping *Shh* expression (308,324). *Bmp2* can induce *Fgf4* expression anteriorly in the AER (325,326). Shh can induce *Bmp2* expression, and *Bmp7* expression is induced in a dose-dependent fashion (309). BMP signaling may be quite complex as at least *Bmp2*, *Bmp7*, and *Bmp4* are expressed in the limb, and the molecules may also form heterodimers.

The genetics of human limb malformations was recently reviewed by Zuniga et al. (327). A recent review by Biesecker (328) listed 310 genetic conditions known to be associated with polydactyly, 290 of which were considered “syndromic” (i.e. associated with other malformations). Of these 310 genetic conditions, the causative genes have been identified in only 80 of these conditions, which suggest that much remains to be learned about the genetics of limb development and malformation.

## 15.10 CONCLUSION

Human development requires the precise regulation of a large but finite number of genes in the different developing tissues and organs, both in terms of where the genes are expressed and when they are expressed. Malformations in one or more organ systems occur when these genes are mutated and thereby disrupting the evolutionary-conserved sequence of development.

### Biographies

**Wen-Hann Tan** is an attending physician in Genetics at Boston Children's Hospital and a clinical investigator in the Angelman syndrome group within the Angelman/Rett/Prader-Willi syndromes consortium in the NIH Rare Diseases Clinical Research Network, leading the study site at Boston Children's Hospital. He graduated from the University of Nottingham Medical School and completed a rotating internship in internal medicine, adult surgery, and pediatrics. He then undertook pediatric residency training in England and at Massachusetts General Hospital, followed by a residency in medical genetics in the Harvard Medical School Genetics Training Program. He is board-certified in pediatrics and clinical genetics, and he was also admitted to the Royal College of Paediatrics and Child Health (equivalent to pediatric board certification in the United Kingdom). In addition to his clinical interests in Angelman syndrome and pediatric cancer predisposition syndromes, he is also actively involved in projects that attempt to identify genes in novel genetic syndromes through whole-exome sequencing.

**Edward Gilmore** is an Instructor in Pediatrics at Case Western Reserve University and Rainbow Babies and Children's Hospital in Cleveland, Ohio, where he has his own laboratory and sees patients clinically. He received his BS in Molecular Biology at the Ohio State University. He received his MD and PhD at Case Western Reserve University where he studied neuronal migration defects in mice. He trained in Pediatrics at Children's Hospital of Michigan (Wayne State University) and in Pediatric Neurology at Massachusetts General Hospital (affiliated with Harvard Medical School). Prior to his recent move to Case Western Reserve University, Dr Gilmore undertook postdoctoral training at Children's Hospital Boston (affiliated with Harvard Medical School) studying the neurogenetics of brain malformations and was concurrently an attending physician in pediatric neurology at Massachusetts General Hospital. Dr Gilmore is board-certified in neurology with special qualification in child neurology. His clinical interests include the neurogenetics of brain malformations and his laboratory studies the requirements for DNA repair in the nervous system.

**Hagit N Baris** is the Deputy Director of the Recanati Genetic Institute and the Head of the Gaucher Center and Adult Genetics Clinic at Rabin Medical Center in Israel. She received her MD from Sackler School of Medicine, Tel Aviv University, where she is now a lecturer in Pediatrics. She completed her residency in Pediatrics at Sapir Medical Center in Israel and her Medical Genetics residency in the Harvard Medical School Genetics Training program. She is board-certified in pediatrics in Israel and in medical genetics in Israel and the United States. She has an interest in Gaucher disease and in the genetics of cardiovascular diseases.

### 16.1 INTRODUCTION

Humans have always been fascinated by twins. They are the makings of legends and “old wives’ tales.” Mythology is full of tales of twins. Romulus and Remus, said to be the founders of Rome, were twins who were supposedly nursed by a she-wolf. The two brightest stars in the Gemini constellation, Castor and Pollux, are named after a pair of mythologic twins. Conjoined or “Siamese” twins have also fascinated humans and used to be part of circuses and sideshows, where they were displayed as oddities or “freaks of nature.” The most famous pair of conjoined twins were Chang and Eng from Siam (hence the term Siamese twins), who were exhibited in an American circus for many years.

Throughout history, different cultures have had different attitudes regarding twins. In some, the birth of twins was thought to be good luck and to predict times of abundance, giving the family a special place in the community. In other cultures, the birth of twins was thought to be a bad omen, and both the twins and the mother were often rejected by the community or even killed. With time, as scientific and medical knowledge have increased, the opportunity to study similarities and differences within twin pairs has led to numerous scientific advances (1–3).

### 16.2 DETERMINING ZYGOSITY

Twins can be either dizygotic (DZ) (also called “fraternal”) or monozygotic (“identical”). DZ twins are the result of two different ova fertilized by two different sperm growing and developing at the same time in the same uterus. MZ twins are the result of one ovum fertilized by one sperm that divides to form two embryos (4,5). In the past, the only way of differentiating between

MZ and DZ twins at birth was their sex and appearance. If twins were of unlike sex, they were said to be DZ, whereas if they were like-sexed and looked identical, they were said to be MZ (5). Although not always definitive, placentation was another means of establishing zygosity (4). Other methods that have been used to differentiate between MZ and DZ twins include blood types, blood protein polymorphisms, human leukocyte antigen (HLA) typing, and dermatoglyphic studies that document fingerprints, palm prints and creases. More recently, DNA analyses have been used to establish zygosity. Notably, zygosity assessment based on physical similarity has been shown to be approximately 95% accurate (6).

A statistical approach to establish zygosity for population studies was proposed by Weinberg (7), who used the Weinberg differential method to estimate the number of MZ and DZ twin pairs. This method assumes that all MZ twins are like-sexed. It also assumes that in DZ pairs the sex of twin pairs occurs at random, so that one half is like-sexed and one half is unlike-sexed (i.e. in one-fourth of DZ twin pairs both are female, in one half there will be male/female pairs, and in one-fourth both twins are male). Thus, if A is the number of like-sexed twins and B is the number of unlike-sexed twin pairs observed, the estimated proportion of MZ twin pairs would be  $(A - B)/(A + B)$  and the estimated proportion of DZ twin pairs would be  $2B/(A + B)$ . The reliability of the Weinberg method has been questioned by new evidence. For instance, unlike-sexed twins are not always DZ, as when one is 46XY and the other is 45X (8–10).

Today, sex, placentation, cord blood type, HLA antigens, and DNA analysis, including DNA fingerprinting (11–13), DNA microsatellites (14) and, recently, single nucleotide polymorphisms (15), are all used to

differentiate between MZ and DZ twin pairs, with DNA analysis now being the most accurate method for determining zygosity. The analysis of DNA from cells such as fibroblasts or buccal cells may be more accurate than analyzing DNA from blood cells, as chimerism of blood supply is known to occur in both DZ and MZ twins (16,17).

### 16.3 INCIDENCE OF TWINS

The incidence of MZ twins had been thought to be constant throughout the world. In contrast, the incidence of DZ twins was known to vary from population to population (18), with a higher prevalence in some areas, such as Nigeria (19,20), and a lower prevalence in other areas, such as Japan (21,22). The prevalence of MZ twins had been reported to be remarkably constant and was not observed to be affected by environmental or maternal factors until recently. The incidence of twins (the combination of MZ and DZ) in North America was estimated at 10–15 in every 1000 births, that is, roughly one in every 80 births (23). This meant that approximately one in every 40 people in North America was born a twin. There does seem to be seasonal variation, with peaks in March to June and September in the Northern Hemisphere (24). However, the incidence of twins has increased over the past few decades, to almost one in 36 live births. This mostly represents an increase in DZ twins, due to the increase in older mothers and the use of assisted reproductive technologies (ARTs) (25–28); however, MZ twinning also increases with the use of ARTs (29,30).

Data from several countries suggest that the spontaneous rate of MZ births may be increasing as well (31–33). A number of studies have suggested an increase in twin births because of periconceptual vitamin intake (34), particularly increased levels of folic acid (35,36), but other studies have failed to replicate such findings (37,38). The mechanism(s) for the increase in live births of twins is unclear but may reflect improvement in the living environment and better nutrition in the general population (39). The number of twin conceptions is hard to assess, as studies have shown that at least 70% of twin pregnancies diagnosed by ultrasound examination before the tenth week undergo miscarriage or convert to singleton pregnancies (40,41). The disappearance of a co-twin has been termed the vanishing twin.

### 16.4 VANISHING TWIN

Up to 70% of all conceptions, including twin conceptions, are lost prior to live birth, mostly because of either implantation failure or early pregnancy loss (42,43). Several studies have shown that the number of twins in spontaneous abortuses is three times more frequent than that in live births (44,45). Estimates of vanishing twin rates vary, depending on the time (i.e. how early)

and the number of ultrasound scans performed. Several investigators have confirmed that the number of twins at delivery is considerably less than the number of twin conceptions seen on ultrasound examination in early pregnancy (40,46–48).

Twin pregnancies resulting from in vitro fertilization have also shown that the number of twins seen at birth is lower than that seen on ultrasound in early pregnancy (49). However, studies of corpora lutea in spontaneous twins suggest that DZ twins do not seem to have an increased spontaneous miscarriage rate, so the observed excess loss may well be primarily among MZ twin conceptions (50).

The greatest “disappearance” of the co-twin recognized by ultrasound examination seems to occur during the first trimester. The earliest loss may not be detectable by current methods. Some of the mechanisms that have been suggested for the vanishing twin include vascular compromise, life-threatening malformations, spontaneous mutations incompatible with life (40), and cord entanglement (48), all of which might be expected to be more common in MZ twins.

### 16.5 STRUCTURAL DEFECTS IN TWINS

Both MZ and DZ twins are known to have an increased risk for structural defects compared to singletons (51,52). Deformations are particularly increased presumably because of the external pressure due to two growing fetuses sharing the space usually meant for one. However, all anatomic sites appear to be involved in the overall increase rather than just those expected to be increased by external compression. Structural defects in MZ twins are three times more frequent than among DZ twins and two to three times more frequent than seen in singletons (53–55). The structural defects seen in MZ twins can be divided into three groups (Table 16-1) based on the type of process producing them. Because of the high rate of structural anomalies in twins, and the high rate of conversion of a twin pregnancy to a singleton (see below), many singletons born with congenital anomalies may have started as part of a twinning process.

### 16.6 TWINS IN GENETIC STUDIES

Classical twin study methods (56) rely on the assumption that MZ twins are genetically identical; therefore, any discordance between them would be expected to be due to environmental influences, whereas differences within DZ twin pairs are thought to be due to a combination of both genetic and environmental factors. For the most part, the assumption that MZ twins are identical genetically is probably correct, but there are increasing numbers of reports of discordance, for disease (see Table 16-5) and for epigenetic factors such as DNA imprinting and methylation (57). However, the extent to which epigenetic discordance will influence a given trait is unclear.

**TABLE 16-1 Structural Defects in Monozygotic Twins**

Associated with the Twinning Process Due to Incomplete Splitting of the Embryo	Due to Shared Vascular Connections or to <i>in Utero</i> Death of Second Twin	Due to Fetal Constraint or Crowding <i>in Utero</i>
Conjoined twins Fetus <i>in fetu</i> Fetus papyraceous	Acardia (TRAP sequence) Asplenia Microcephaly, hydrocephaly Intestinal atresia Aplasia cutis Terminal limb defects Gastroschisis Disseminated intravascular coagulation	Craniosynostosis Positional defects of the foot Bowing of the limbs Some contractures

There are many types of studies in which twins can provide valuable information. The approach is particularly useful because it can deal with many variables simultaneously. Many twin registries have been set up for this purpose (58). Usually the purpose of twin studies is to obtain results that are applicable not only to twins but also to the whole human population. However, when using twin methodologies, it is necessary to determine whether twin and singleton populations differ in the mean or variance for the trait under study, because a background difference may alter the interpretation of the conclusions (59). It is assumed that MZ and DZ twins are exposed to the same pre- and postnatal environmental factors, which may not be true. Machin and colleagues (60) suggest that the intra-uterine blood supplies to each individual of an MZ twin pair may be markedly different and that the two twins in an MZ pair may start with very different cell numbers (61,62). Studies of MZ twins reared apart have been helpful in establishing the significance of genetic and environmental factors regarding susceptibility to complex psychiatric disorders such as schizophrenia (63), nightmares (64), and manic depressive disorders (64), as well as to measure the extent of inherited versus environmental contribution in disorders with multifactorial inheritance. Thus, twin studies may help to sort out the genetic aspects of a variety of phenotypic traits and disorders with multifactorial inheritance (termed complex traits/diseases) (2,65–67).

## 16.7 DIZYGOTIC TWINS

DZ twins are derived from the fertilization of two ova by two sperm and may be of the same or different sex (68). Their genetic contribution is different because it comes from two different ova and two different sperm (69) (e.g. two siblings who happen to be in the same uterus at the same time). DZ twinning is a common occurrence in animals. Many mammals are known to have sizable litters, almost always due to polyovulation, making every member of a litter a DZ twin.

Multiple ovulation, the release of more than one ovum from the ovaries, is necessary for DZ twinning. Women with a history of DZ twinning have an increased

incidence of multiple follicle growth (70,71), and two corpora lutea can be seen on ultrasound in DZ twin pregnancies (72), with twin ovulations occurring from different ovaries about half the time (50). Women who have given birth spontaneously (i.e. without the use of fertility drugs) to DZ twins are known to have higher levels of follicle-stimulating hormone (FSH) and luteinizing hormone than are found in those who have delivered singletons (73,74). Increased DZ twinning in older women is thought to result from depletion of the ovarian follicle pool and subsequent rise in concentrations of FSH (75,76).

### 16.7.1 Types

DZ twins produced by the fertilization of multiple ova may also be the result of superfecundation. Superfecundation occurs when two different ova are fertilized by two different sperm in more than one act of coitus. In a case reported by Archer (77), one twin was white and the other black; in another case (78), the twins were significantly discordant in size and development at birth. DNA-based paternity testing has revealed additional cases (79,80). DZ twins may also arise from superfetation. Superfetation occurs when a second fertilized ovum implants in a uterus already containing a pregnancy of at least 1 month (69). Superfetation has been suggested in some cases in which the twins are markedly discordant for birth weight, supposedly due to different gestational ages (69,81). A case of superfetation was recently detected following ART in a woman with an undiagnosed ectopic pregnancy (82).

Other types of DZ twinning have been proposed, but in reality these are exceptionally rare and may not be compatible with life. Polar body twins are thought to arise from the simultaneous fertilization of the meiotic products of the same primary oocyte, the oocyte and a polar body, by two different sperm (81). Polar body twinning has not yet been reported in live-born DZ twins but has been suggested in one case as a cause for acardia (83) that was triploid. “Semi-identical” twins, where twins are identical for their mother’s genotypes but not

for their father's, have also been reported; they are the result of two sperm from the same father fertilizing one ovum that split either just prior or subsequent to fertilization (84,85).

### 16.7.2 Placentation

By definition, DZ twins would be expected to have two placentas, with two chorions and two amnions, that is, they would be diamniotic dichorionic (60). However, placentas in DZ conceptions may fuse and look like one placenta. In cases of fused placentas, DZ twins often have vascular connections (86). van Dijk and colleagues (87) have demonstrated chimerism in 8% of DZ twins using sensitive immunological techniques, suggesting that these DZ twins will have immunologic tolerance and be good transplantation donors for each other (88). Bianchi suggests that direct placental connections may not be necessary for microchimerism in DZ twins (16). Careful pathologic and histologic examination of the placenta and other membranes will help in establishing the zygosity of a twin pregnancy (60,89), although nowadays zygosity is most accurately established by DNA analysis. Cases of monochorionic diamniotic DZ twins have been reported associated with ARTs (90,91) and spontaneous DZ twin pregnancies (92). These cases can be particularly confusing because chimerism can occur so that DNA studies based on blood samples appear to predict MZ twinning (93,94).

### 16.7.3 Incidence

The spontaneous incidence of DZ twins varies from country to country (19). However, because of the lack of accurate distinction between MZ and DZ twins, most countries report combined twinning rates. If the MZ twinning rate is assumed to be constant, the variation is thought to reflect DZ twinning rates. Asia, particularly Japan, has the lowest reported twinning rate (2–7 per 1000 births) (21). A slightly higher twinning rate has been reported in Europe (9–20 per 1000 births). The highest twinning rate is seen in the black African population, where it is estimated to be as high as 45–50 per 1000 births (20). The DZ twinning rate in North America is generally estimated at 7–11 per 1000 births (18). The DZ twinning rate is closely related to increasing maternal age, particularly over the age of 30 years (95,96), and peaks around the age of 35–39 years; higher parity is also independently associated with a higher DZ twinning rate (97,98). Tall heavy women are more likely to give birth to DZ twins than short thin women (99–101). DZ twinning has been associated with relatively high levels of gonadotrophin (leading to excess ovulation). Maternal smoking has been suggested to play a role in DZ twinning (100,102).

The DZ twinning rate has increased steeply since the lowest recorded rates in the 1970s (103), coincident with the increased use and improvements in ARTs. In North America, approximately one in 100 births has been of DZ twins and one in 50 individuals was born as a DZ twin: now 1%–2% of pregnancies are achieved through ARTs (as many as 3%–4% in Europe and Australia), and one-third of these result in multiple births. However, most of the increase has been attributed to older maternal reproductive age, both among mothers who conceive twins spontaneously (responsible for 50%–60% of the increase) and those undergoing ART procedures (28,104,105).

Lewis and colleagues (106), using the Australian twin registry, have shown a major genetic contribution to the occurrence of spontaneous DZ twinning. They point out that multiple ovulation does not always result in a live-born DZ twin because of the high spontaneous background loss rate that occurs in one of the twins; nevertheless, increased multiple ovulation is likely to lead to increased fertility. A gene for increased fertility therefore could be expected to have a selective advantage. They suggest that a single gene responsible for DZ twinning would be expected to be quite frequent in the general population if it confers a selective advantage (e.g. more individuals who survive born with the trait). Meulemans and colleagues (107), analyzing European twin data, also suggested a single autosomal dominant gene model for DZ twinning. The total evidence accumulated to date, however, suggests that inherited DZ twinning is likely to be a multifactorial complex genetic trait, influenced by a number of genes.

### 16.7.4 Familial Dizygotic Twinning

There are many reports of familial DZ twinning (108). The female members of these families are thought to have an inherited predisposition to multiple ovulation and in turn have a higher number of DZ twin pairs when compared to the general population (107). The risk of having twins is up to 2.5 times higher for a woman with a sister with DZ twins than it is for the general population (69,106). An established association between higher gonadotrophin levels and higher incidence of DZ twins in certain families is thought to be the basis for familial DZ twinning. While there appears to be some controversy whether this is an autosomal maternal or paternal effect (106,109), in reality a twinning gene could be inherited through either the maternal or paternal side, although it will only be expressed in females. It is possible that some genetic disorders may also predispose to DZ twinning (110).

### 16.7.5 Genetics of Dizygotic Twinning

Studies of species other than humans have revealed a number of genes that contribute to DZ twinning. The

study of sheep has proved particularly informative, as sheep typically give birth to a single offspring at a time but some strains have high incidences of multiple births (111). To date, three genes have been confirmed to influence DZ twinning rates: the growth differentiation factor 9 (*GDF9*) and bone morphogenetic protein 15 (*BMP15*) genes, both of which are expressed in the oocyte and essential for follicle development, and the bone morphogenetic protein receptor 1B (*BMPR1B*), the receptor for *BMP15* and expressed in multiple cell types in the ovary. Interestingly, while mutations in *GDF9* and *BMP15* can increase twinning rates when one copy is present (i.e. when the mother is heterozygous for the mutation), they can also cause female *infertility* when two copies are present in one individual (i.e. in homozygous form) (112,113).

At present, only mutations in *GDF9* appear to influence human DZ twinning, although such mutations are rare. Screening these genes in large numbers of DZ twinning families has revealed a loss-of-function mutation and a two-base deletion in *GDF9* in heterozygous form in three families (114,115), and it appears that overall genetic variation in *GDF9* is more common in mothers of DZ twins than it is in controls (115). No such effect has been found for *BMP15* (116) or *BMPR1B* (117). Interestingly, both *GDF9* and *BMP15* have been implicated in premature ovarian failure (118).

There are a number of additional genes known to have roles in ovulation but as yet there is little evidence that these have anything more than a minor, if any, role in human DZ twinning (25). Genetic variants that result in changes in amino acids in the follicle-stimulating hormone receptor (FSHR) protein were suggested to contribute to DZ twinning (119) but further studies found no evidence for the involvement of this gene (120). Likewise, evidence for the involvement of serine proteinase inhibitor clade A member 1 (*SERPINA1*, commonly known as alpha-1-antitrypsin; (121,122)), peroxisome proliferator-activated receptor gamma (*PPARG*; 46) and the fragile X (FRAXA) “premutation” (123,124) has not been borne out in later studies (25). Family-based “linkage” studies have found no evidence for increased levels of genetic sharing among family members over chromosomal regions in which such candidate genes are located (125–127).

Linkage studies have, however, indicated chromosomal locations that may harbor new candidate genes for DZ twinning (125,127,128). A recent study including 525 DZ twinning families suggests the presence of

such genes on a number of chromosomes, most notably chromosomes 6, 12 and 20, in Australian and Dutch DZ twinning families and confirmed that DZ twinning is a complex trait likely to be influenced by multiple genes (127). Interestingly, a variant with a known functional effect located in the promoter of the *FSHR* gene was found to segregate with the DZ twinning phenotype in one large family, although whether this variant influenced DZ twinning in this family remains to be investigated. Much work remains to be done to find the genes underlying the tendency to human DZ twinning.

## 16.8 MONOZYGOTIC TWINS

MZ twins are the result of the fertilization of one ovum by one sperm. The single fertilized ovum (zygote) then divides into two embryos; both embryos are thought to initially have the same genetic contribution and in the past have been expected to be genetically identical. However, with new molecular genetic techniques, it has become clear that some MZ twins are not completely genetically identical (57,129,130). MZ twins have been described as natural clones; however, this is incorrect. In the course of the development of every large multicellular organism, somatic mutations as well as epigenetic and stochastic processes lead to distinct genetic differences between MZ twins (131). MZ twinning (as compared to DZ twinning) is rare among nonhumans, where most multiple births represent polyovulation rather than splitting of a zygote. For instance, McLaren and colleagues (132) found no evidence of MZ twinning among 1247 pups born following spontaneous or induced ovulation, suggesting that MZ twinning in mice is either extremely rare or that both members of an MZ twin pair rarely survive to weaning.

### 16.8.1 Types of Placentation

The type of placentation in MZ twins is thought to correspond to the stage in embryonic life during which the twinning event occurred (Table 16-2; Figure 16-1); the later the timing of the event, the more likely the twins are to be monochorionic, monoamniotic, or even conjoined (60,68). There are a number of different types of placentation according to the number of chorionic membranes and amniotic sacs. MZ twins may have separate or contiguous placentas and may be monochorionic monoamniotic (extremely rare with a poor outcome because of tangled umbilical cords; <1% at birth), monochorionic

**TABLE 16-2** Types of Monozygotic Twins According to Placentation

Types of Placentation in MZ Twins	Time of Division after Fertilization (Days)	MZ Twin Pregnancies Surviving at Birth (%)
Dichorionic diamniotic	<3	25
Monochorionic diamniotic	4–6	70–75
Monoamniotic monochorionic	7–13	1–2

**FIGURE 16-1** Process of monozygotic twinning during postfertilization. Ovul, ovulation; fert, fertilization; divis, division; blast, blastulation.

diamniotic (almost uniformly with vascular connections, about 70% at birth), or dichorionic diamniotic (with separate or contiguous placentas, about 30% at birth) (see Table 16-2). There is likely to be increased loss (of the pregnancy or of one twin) among the types of placentas with vascular connections (48,133), and the frequency of various types of MZ chorionicity at conception is unknown. In the case of contiguous placentas, MZ twins often share vascular connections and circulation. About 75% of MZ twins surviving to birth are thought to have had vascular connections in utero.

## 16.8.2 Incidence

The incidence of MZ twins in humans had been thought to be constant throughout the world, at 3–4 in every 1000 births (20,21). This meant that approximately one in 300 births has been an MZ twin birth and one in 150 individuals has been born as an MZ twin. The rate of MZ twinning appears to be unaffected by maternal age, parity, height, or weight (31). Although temperature, delay from the time of ovulation until fertilization or implantation, oxygen supply, and various teratogenic agents have been shown to affect MZ twinning rates in other animals (134), no such factor has been associated with MZ twinning rates in humans. A recent association between an increase of twin births (both MZ and DZ) and periconceptual vitamin supplementation, specifically folic acid, has been reported by Czeizel and colleagues (34), suggesting that adequate maternal nutrition is important for survival to birth for human twins (e.g. loss or conversion to singleton may occur with inadequate nutrition). The population rate of spontaneous MZ twins seems to be increasing (31) and a 3–5 times increase in MZ twin births has been seen with in vitro fertilization (29,135), perhaps related to ovarian stimulation, disturbance of the zona pellucida, or

culturing conditions or handling (e.g. blastocyst transfer) during ART procedures (29). MZ twins and MZ triplets are frequent among spontaneous triplets (136).

## 16.8.3 Familial Monozygotic Twinning

There have been a number of reports of families in which MZ twinning occurs more frequently than expected (137–141), which has been termed familial MZ twinning. Interestingly, there does not seem to be an increase in congenital anomalies among the MZ twins in these families. Because familial MZ twinning has been reported on both the maternal and paternal sides of the family, it has also been suggested that it may be caused by a single gene effect that is unaffected by the sex of the parent transmitting the gene (140,142). However, data from Lichtenstein and colleagues (109) have suggested that there is no paternal effect on familial MZ twinning. Familial MZ twinning could be related to an inherited defect in the zona pellucida leading to early hatching—a mechanism similar to that proposed for the increased rate of MZ twinning seen following ARTs. Alternatively, familial MZ twinning may be related to environmental or epigenetic factors. However, studies on familial MZ twinning are hampered by the possibility of ascertainment bias as such studies typically only include families containing multiple MZ twin pairs.

## 16.8.4 Anomalies Associated with Monozygotic Twin Conceptions and Observed Differences between the Members of an MZ Pair of Twins

Twin pregnancies and twins are at risk for a variety of obstetrical, perinatal, and neonatal medical problems not covered in this chapter. However, MZ twins are

known to have a higher incidence of all types of congenital anomalies (see Table 16-1), and there are also some anomalies that are unique to the MZ twinning process itself. Most of these unique anomalies are thought to be due to defects in the completion of the development of the embryo, such as conjoined twins (2,71,143–145) and fetus in fetu (146,147); vascular aberrations such as acardia (148–151); vascular accidents such as terminal limb defects and death of the co-twin (152); and fetal constraint (which occurs in both types of twins) (Table 16-3). The intrauterine environment may be different for the two MZ twins of a pair because of the number of cells allocated to each twin, the timing of the twinning event, and the placental vascular supply to each twin (60,89). Interestingly, in utero studies of MZ twin behavior have recently shown clear differences in activity and responsiveness before 20 weeks of the pregnancy (153).

It is becoming clear by studying MZ twin pairs that a number of neurologic, immunologic, and structural aspects of embryogenesis appear to be independent of genetic factors. Steinmetz and colleagues (154) have described the discordance in brain surface anatomy in MZ twins. Wolf and colleagues (155) and Trejo and colleagues (156) have shown differences in the immune response between MZ twins in spite of exposure to very similar in utero and postbirth environments. Somatic changes have been observed to occur in the course of development of the MZ twins, leading to differences between the MZ twins in telomere length (157), the fragile X triplet repeat expansion (158), and Alu band variants (159).

### 16.8.5 Mirror-Image Twins

Some MZ twins have features that appear to be mirror-imaged. The most common differences are minor

asymmetries of facial features, such as the side of upsweep of the head hair or eyebrow, one-sided ptosis, or the side of eruption of the first tooth (160–162). A very interesting hypothesis regarding mirror-image twins was made by Boklage (163–165), suggesting that MZ twinning sometimes requires readjustment of the body axis plan. Sperber and colleagues (162) suggest that mirror-image twinning may occur relatively late in embryonic development after the orientation of axis of the zygote has been established but early enough to avoid conjoined twins.

### 16.8.6 Sex Ratio in Monozygotic Twins

The sex ratio (the proportion of males compared to the combination of males and females) among MZ twins is lower than that among DZ twins or singletons (166,167) (Table 16-4). Conjoined twins have an even lower sex ratio than MZ twins (68,168), meaning that there is an excess of female conjoined twins. Tsunoda and colleagues (169) showed in mice that female embryos are behind male embryos in the number of cells present at a specific stage in early development, suggesting that female conceptions may be at higher risk, because of their delayed embryonic development, for late splitting of the embryo, leading to the observed excess of conjoined and MZ twins. Interestingly, there is an excess of same-sex twins among DZ twins.

### 16.8.7 Phenotypic and Epigenetic Discordance in Monozygotic Twins

Although typically considered genetically identical, there are increasing numbers of publications reporting discordance for phenotypic and genetic factors between the twins of an MZ pair. This is most clearly seen when twins are discordant for disease (Table 16-5),

**TABLE 16-3 Anomalies Exclusive to Monozygotic Twins**

Anomaly	Description	Reference
Fetus <i>in fetu</i>	Small parasitic dead twin attached to a normal twin. Often confused with a tumor. Generally located at the origin of the superior mesenteric vessels. Other sites have been reported.	(146,147) MacGillivray et al.
Fetus papyraceous	Mummified dead fetus usually attached to the placenta and present with a normal or more viable twin.	(133,152)
Acardia	Twin with an absent or rudimentary or nonfunctioning heart and whose circulation has been sustained by a normal twin. Associated with a higher rate of chromosomal anomalies (1 in 35,000 births with excess of females).	(55,151)
Conjoined twins	Incomplete twins resulting from an abnormality of the twinning process. They are derived from a single zygote and are always of the same sex. Incidence varies from one to 20,000 to one to 100,000. Females make up 80% of conjoined twins.	(69,143,144,210)

**TABLE 16-4 Sex Ratio in Twins**

for example X-linked Duchenne muscular dystrophy (170,171), autosomal Mendelian diseases such as familial amyloid polyneuropathy (172), and complex diseases such as autism (173). Alternatively, both twins may be diagnosed with the same disease but manifest different symptoms or timing of disease onset (174–176). Magnetic resonance imaging has recently shown discordances in brain development and anatomy (177,178). Underlying causes may include discordance for chromosomal aneuploidy (179–181), uniparental disomy (182), chromosomal rearrangement (183), triplet expansion (184) or nuclear (185,186) or mitochondrial (187,188) point mutations that have occurred postzygotically (57).

Recent advances in genetic technology have revealed further areas of MZ twin discordance, at the level of the DNA sequence (for example copy number variants (189)), gene expression (190), and epigenetics, particularly DNA methylation (191). Epigenetic phenomena, now known to be key regulators of gene expression, change dynamically over time and under different environmental conditions, and studies have now shown increasing discordance between MZ twins with increasing age and lifestyle differences (192,193). Discordance in telomere length has also been shown to increase with age (194).

### 16.8.8 Etiology of Monozygotic Twinning

The etiology of MZ twinning in humans is unknown, but several mechanisms have been proposed. Stockard (145) suggested that MZ twinning may be due to lack of oxygen prior to implantation, which caused developmental arrest and splitting in the zygote. His work was supported by the finding that the implantation of the ovum is delayed in the armadillo, which results in MZ quadruplets or octuplets (195), and by studies in rabbit and roe deer showing that twinning in these animals is also associated with delayed implantation (69). These findings suggested that MZ twinning is associated with disturbance of development clocks or thresholds and that delayed fertilization or delayed implantation may play a role in MZ twinning.

On the basis of observations of a higher-than-expected incidence of MZ twins after *in vitro* fertilization (12,196), Edwards and colleagues (197) suggested that abnormalities or rupture of the zona pellucida may lead to herniation of the blastocyst and predispose to MZ twinning (198). Boklage (160,164,165) pointed out that differentiation of the chorion occurs at approximately the fourth day after fertilization and that, in monochorionic MZ twins, the physical separation of two embryos is unlikely if the zona is still intact when the chorion begins to develop. Boklage suggested that if the zona is intact, rather than a physical separation of the MZ twins, there may be “developmental” separation, rendering two groups of cells within a morula that organize themselves separately and continue with embryogenesis separately.

Other investigators have suggested that twinning itself may be a type of congenital anomaly or an abnormality of development, with the “twinning” fertilized egg (i.e. a fertilized egg resulting in twins) developing at a different rate and in a different way, as compared to a “normal” fertilized egg (i.e. an egg resulting in a singleton). There must be a relatively narrow window during which MZ twinning can occur (normally only up until 11–13 days postfertilization, when the primitive streak forms), and there are a number of different events taking place during postfertilization, including hatching, implantation, genomic imprinting, and X-inactivation (see Figure 16-1). If the twinning zygote is maturing at a different rate than the normal zygote, the timing for all these events may be shifted and may even occur in an order different from the predicted normal timing for singletons.

The finding that mammalian female embryos are somewhat behind male embryos in the number of cells present at a certain stage during early stages of embryonic development (169) and the fact that there is a slightly higher incidence of female MZ twins, particularly among conjoined twins, in which the twinning process is assumed to occur relatively late in the very early embryonic developmental process support the suggestion that MZ twinning is somehow related to delayed implantation and that the timing of different developmental clocks plays a critical role in MZ twinning.

Several authors (4) have suggested that skewed X-chromosomal inactivation may play a role in female MZ twinning if, during embryogenesis, two different foci were to arise: one expressing the maternal X and the other expressing the paternal X. A number of female MZ twins have been discordant for a variety of X-linked recessive diseases (199), suggesting, and often demonstrating, nonrandom X-inactivation (Table 16-5). Goodship and colleagues (171) have tested the hypothesis that skewed X-inactivation can trigger MZ twinning in females by studying umbilical cord tissue in female MZ twins. They observed random X-inactivation in most pairs of female MZ twins, but some showed marked skewing. Thus, it would appear that skewed X-inactivation does not explain all female MZ twinning but could be responsible for the excess of MZ female twins. Interestingly, Tan and colleagues (200) have shown that X-inactivation occurs at different times in different tissues postimplantation in the mouse embryo. These findings suggest that since X-inactivation occurs at the time of tissue differentiation, X-inactivation in blood and skin may not be representative of the rest of the tissue in an organism. To properly determine the exact role of X-inactivation in female MZ twinning, it would be necessary to study many different tissues. Bamforth and colleagues (201) have studied the parent of origin of X-inactivation in placental membranes and umbilical cords in twins and triplets. The chorion did show asymmetric X-inactivation in MZ dichorionic

twins. Of course, the chorion is not representative of the whole embryo but may represent processes that occurred early in development. The study also suggested that monochorionic MZ twins may react differently from dichorionic ones, reflecting the importance of timing in the MZ twinning process.

Observations of discordance in the expression of genetic material in MZ twins (see Table 16-5) have suggested the intriguing possibility that some cases of MZ twinning may occur because of epigenetic events (105,202), such as a discordance in the expression of genetic information, not only by discordance of X-inactivation but also by many other mechanisms, including genomic imprinting (203,204), loss of imprinting, the development of uniparental disomy (182), changes in chromosome number, mitochondrial mutations (202,205,206), and telomere crossover (207) and length (208). Weksberg and colleagues (209) found differential imprinting in female MZ twins discordant for Beckwith–Wiedemann syndrome and proposed that in such cases either unequal splitting of the inner cell mass or, alternatively, a lack of maintenance of DNA methylation, leads to a loss of imprinting that predisposes to MZ twinning. Such discordance would be expected to arise early in development among cells from a single zygote. A discordance of expression of genetic information could then lead to division of the zygote into two separate embryos during a specific period, early in development, perhaps from the stage of eight cells to approximately 360 cells in the inner cell mass, when differentiation and primitive streak formation begins. After birth, this discordance of genetic information could be mosaic in each twin, but it could be present to different degrees in the two different twins sufficient to cause observable phenotypical discordance. In other words, once measurement error and environmental influences are accounted for, genetic discordance or differences in the expression of genetic information should be suspected in cases of discordant MZ twins.

## 16.9 CONCLUSIONS

In the field of twins and twinning, there is still a great deal to be learned. The development of new DNA molecular and cytogenetic techniques, the use of prenatal diagnosis such as chorionic villi sampling, amniocentesis, and ultrasound examination in humans, as well as embryopathology, histology and genetic advances all give clues to the increased understanding of MZ and DZ twins and the twinning process itself.

# CHAPTER 17

## The Molecular Biology of Cancer

*Edward S Tobias*

Wolfson Medical School Building, University Avenue, Glasgow, UK

### 17.1 INTRODUCTION

Cancer is a genetic disease, arising from the progressive accumulation of mutations that promote the clonal selection of cells with increasingly deregulated growth. Studies from many different fields, including tumor virology, chemical carcinogenesis, molecular biology, somatic cell genetics, and genetic epidemiology, have all provided fundamental insights into the genetic basis of cancer. Most of these alterations are somatically acquired, but some are inherited. During the last four decades, many of the genetic targets of the mutations have been identified. The cancer phenotype, however, is a result of complex interactions, not only involving the known cancer gene products but also a multitude of other proteins.

An increasing number of “modifier” genes and low-penetrance cancer susceptibility gene variants are being discovered, such as the breast cancer risk modifier genes, *FGFR2*, *CASP8*, *MAP3K1*, *TOX3/TNRC9* and *RAD51* genes (Milne and Antoniou, 2011), and the colorectal cancer (CRC) risk modifier variants in the *APC*, *TP53*, *IGFBP-3*, *TCF7L2* and *TGFBR1* genes (Jasperson et al., 2010). The relative risk attributable to any one of these genes is generally small compared to that of the known high-penetrance cancer genes, but collectively their variant alleles may strongly influence an individual’s cancer risk. Additionally, all these interactions are subject to modification by incompletely understood environmental factors. The disentangling of all such interrelations poses a major challenge to cancer biologists.

Most known cancer genes fall into three broad classes: proto-oncogenes that are positive regulators of cell proliferation and survival; tumor suppressor genes (TSGs) that are negative regulators; and DNA repair genes that are responsible for the detection and repair of genetic damage. The coordinated regulation of these gene classes is responsible for maintaining tissue homeostasis. Cancer reflects a fundamental breakdown in this control. The types of alteration that occur in proto-oncogenes and TSGs display intrinsic differences. Point mutations in proto-oncogenes are usually missense

and tend to activate—or give new functions to—the gene product. Alternatively, proto-oncogenes can be amplified or can undergo translocations that either place them under the control of active promoter sequences or generate a fusion product with a new or constitutive function. Oncogenes are thus proto-oncogenes that have undergone gain-of-function alterations that act in a positive fashion to promote tumorigenesis. TSGs, on the other hand, are subject to loss-of-function alterations, commonly through point mutations that truncate the protein product (or alter a crucial functional domain) or through deletions. These differences partially account for the dominant tumorigenic activity of oncogenes and the usual recessiveness (at the cellular level) of tumor suppressors. Many of the cellular genes affected by human cancer-associated mutations (particularly those that are inherited) are discussed in greater detail below.

Many studies have highlighted the critical role of mutations involving the third class of genes in the cancer process; that is, the DNA repair genes, also termed the “stability genes” or “caretaker genes” (Vogelstein and Kinzler, 2004). As with the TSGs, the loss-of-function mutations in these genes are the basis for their role in tumorigenesis. They can be considered as a subset of TSGs, but they differ from other TSGs in critical ways. The protein products of some TSGs may, while functioning normally, provide growth-inhibitory signals or activate cell differentiation pathways. Other tumor suppressor proteins may mediate programmed cell death (apoptosis) following DNA damage or cell cycle perturbations. In contrast, the stability genes encode proteins that either (a) repair (by nucleotide or base excision repair, or mismatch repair) small-scale aberrations in the DNA following DNA replication or the action of mutagens or (b) maintain the normal chromosomal structure such as in mitotic recombination or segregation (Vogelstein and Kinzler, 2004). Therefore, the principal effect of the *inactivation* of DNA repair genes is genomic instability and an increased rate of mutations in a variety of cellular genes, including proto-oncogenes and the TSGs, in affected cells. Because the accumulation of mutations

in these latter two classes of growth-regulating genes appears to be an important rate-limiting step in tumorigenesis, the inactivation of genes that are normally involved in DNA damage recognition and repair greatly accelerates the process of tumor progression.

Given the enormous progress that has been made in furthering our understanding of the genetic alterations present in cancer cells, this chapter does not attempt to review all of the thousands of mutations in oncogenes and the TSGs that have been identified to date in human cancers. Rather, the primary aims of this chapter are (1) to review the historical basis underlying the search for genetic alterations in human cancers; (2) to review the roles of a number of TSGs and a few relevant proto-oncogenes that are associated with inherited cancer syndromes; and (3) to address the molecular biology of some of the more common inherited cancer syndromes resulting from defects in DNA repair genes. An extremely useful continuously updated online database of germline mutations in human disease-associated genes, with multiple links to other similar worldwide databases, is maintained at the Institute of Medical Genetics in Cardiff (<http://www.hgmd.cf.ac.uk>) and at the Diagnostic Mutation Database that is maintained at the Manchester National Genetic Reference Laboratory. Access to these databases requires registration. In addition, online lists of mutations are provided within the appropriate gene-specific OMIM article (within the “Allelic variants” section). In addition, there are several disease-specific online databases of mutations, such as the Breast Information Core (BIC) database of BRCA1 and BRCA2 mutations, the database of HNPCC and FAP-related mutations (freely accessible at the InSiGHT International Society for Gastrointestinal Hereditary Tumors) website, and the Birt Hogg Dube mutation database (see Table 17-1).

## 17.2 A GENETIC BASIS OF CANCER

An inherited basis of some cancers in humans and other animals has been hypothesized for over a century. Broca was perhaps the first to describe an inherited cancer syndrome. In 1866, he described a family with many members affected by breast and liver cancers and suggested that some inherited aberration within the affected tissue allowed tumors to form. Subsequent studies of mammary tumor formation in inbred strains of mice led Haaland, in 1911, to propose that tumorigenesis behaved in a formal sense as a Mendelian genetic trait. Similarly, Warthin’s studies of four families with markedly increased cancer rates led him to propose in 1913 that susceptibility to several cancer types appeared to be transmitted as an autosomal dominant Mendelian trait. Although these and other studies were consistent with the proposal that a genetic basis of cancer might account for familial clustering of cancer, other explanations of these observations were possible (e.g. clustered exposure

to environmental or dietary agents). Moreover, it was argued that the majority of cancers arose as sporadic or isolated cases.

The proposal that cancer might result from somatic alterations in the genetic material of cells was first advanced by Boveri in 1929. He had previously noted that abnormal mitotic divisions and atypical cell masses could be seen in sea urchin eggs fertilized by two sperms. He reasoned that the abnormal masses bore significant similarity to tumors, and thus he hypothesized that cancer might result from cellular aberrations that produced abnormal mitotic figures. Nevertheless, Boveri’s studies provided some insights into the genetic or cellular mechanisms that might give rise to abnormalities in the regulation of cell division.

The studies of Peyton Rous can therefore be viewed as a particularly critical turning point in the search for a genetic basis of cancer development because they provided the first mechanistic insights into the pathogenesis of cancer. In 1911, he demonstrated that sarcomas in chicken (*Galus galus*) could be induced following inoculation with a cell-free filtrate obtained from an independent chicken sarcoma. Nearly 70 years later, it was conclusively demonstrated (by Stehelin et al. in 1976) that the Rous sarcoma virus (RSV) is a retrovirus that induces cancers in chickens because it harbors an altered version of a cellular proto-oncogene known as the *src* gene. Though retroviruses have thus far been implicated in the causation of a limited number of forms of human cancer (e.g. acute T-cell leukemia), their study acquired a much larger significance by providing experimental access to the genetic underpinnings of tumorigenesis.

More recently, it became clear that tumorigenesis in humans is a multistep process, with these steps reflecting underlying genetic alterations that drive the progression into malignancy. It was suggested—in a seminal

publication by Hanahan and Weinberg—that the enormous range of cancer-cell genetic alterations is, in effect, a manifestation of six essential alterations in cellular physiology or functional capabilities (acquired through differing mechanisms) that collectively permit malignant growth. These comprise (1) self-sufficiency in growth signals, (2) insensitivity to growth-inhibitory signals, (3) evasion of apoptosis, (4) limitless replicative potential, (5) sustained angiogenesis, and (6) tissue invasion and metastasis (Hanahan and Weinberg, 2000).

## 17.3 VIRAL ONCOGENES

### 17.3.1 RNA Tumor Viruses and the Identification of Proto-Oncogenes

RNA tumor viruses (also known as retroviral tumor viruses) can be divided into two classes: acute and chronic transforming viruses. The identification of oncogenes began with the studies of acutely transforming retroviruses. Although not oncogenic in humans, these can rapidly induce tumors in animals and transform cells in vitro. In contrast to the chronic transforming viruses, the genomes of the acute transforming viruses contain nucleic acid sequences that have been acquired or transduced from the host cell as a result of genetic recombination. The altered host-derived sequences are termed *viral oncogenes* (*v-onc* genes), and these sequences, although not necessary for the replication of the virus, are directly responsible for its rapid transforming activity. Characterization of the *v-onc* genes present in various acute transforming viruses has led to the identification of many different cellular genes (known as *proto-oncogenes* when in the unaltered state) that have been transduced by various tumor viruses (Table 17-2).

There is no reason to believe that proto-oncogenes are unique in their capacity to be transduced by retroviruses; rather, the proto-oncogenes represent a unique class of genes because of their biological properties. Transduction of other classes of genes does not give rise to acute transforming viruses. Hence, because of their vital role in the generation of acute transforming viruses, the proto-oncogenes might be presumed to represent at least part of the genetic repertoire that might underlie cancer. Moreover, because the *v-onc* genes harbored by the acute transforming viruses represent mutated versions of their corresponding cellular proto-oncogenes, comparison of the two sequences might be expected to provide insights into the means by which oncogenic variant alleles are generated by somatic mutations, such as point mutation, chromosomal translocation, or gene amplification. Subsequent to the discovery that *v-src* has a counterpart in the cellular gene *c-src*, it has transpired that nearly all retroviral oncogenes are transduced cellular proto-oncogenes whose expression and/or activity is increased as a consequence of the transduction process.

Modified from Weinberg, (1994); with permission.

The acute transforming viruses cause tumors at the site of inoculation after short latency periods (e.g. a few weeks in newborn animals), and they are also able to transform cells in culture. The chronic transforming viruses are capable of producing tumors only in hosts in which the virus can replicate. The tumors arise after relatively long latency periods and at specific tissue sites, irrespective of the inoculation site. The differences in the properties of the two classes of viruses can be traced to differences in their genetic content. Chronic transforming retroviruses (such as HTLV1, mouse mammary tumor virus and avian leukosis virus) possess no cellular sequences and instead transform cells by the effects of the random integration of a DNA copy of the virus, termed the *provirus*, into the host cell genome. The provirus can affect the genes in the region of the host chromosome where it integrates. If a host proto-oncogene is contained in the region, provirus integration can alter the structure and/or expression of the proto-oncogene and thus contribute to tumorigenesis. The relatively long latency of the tumorigenic process for the chronic transforming viruses reflects

the low probability that any one integration event will specifically affect a proto-oncogene. Nevertheless, given the infection of the sufficient cells, transformation will be likely to occur, with leukemias and lymphomas being the most prominent tumor types generated by these chronic transforming viruses. Several of the proto-oncogenes that are altered by chronic transforming viruses in animal tumors are also affected in a subset of human tumors by somatic mutations (Table 17-3).

As mentioned above, these chronic transforming retroviruses induce neoplastic transformation after a latency period of months or years, via the integration of the proviral DNA in such a way as to activate specific host target genes: Cellular genes are either brought under the control of the viral LTR or are fused to viral sequences with the consequent production of novel proteins. Knowledge of this led to the prospective use of insertional mutagenesis as a means of identifying novel proto-oncogenes that are consistent targets for proviral insertion. It was suggested that *spontaneous* alteration of any of these genes might account for tumors—including most human tumors—whose initiation is virus independent. The finding that around one in five tumors possesses genomic sequences with intrinsic transforming ability supports this hypothesis. Indeed, tumor gene transfer experiments (see “Oncogenes Identified by DNA Transfection”) identified oncogenes already known to be the cellular counterparts of various retroviral oncogenes, in addition to several novel genes (many of which belonged to the *src* and *ras* superfamilies). The presence of activating alterations in many of these cellular genes was, in fact, subsequently demonstrated. Other oncogenes were identified directly through their association with translocations, which caused activation either by the generation of new fusion products or by bringing the proto-oncogene under the transcriptional control of nearby enhancer elements. Probes and primers derived

from the oncogenes identified in these various ways were then used to isolate further, homologous, genes by cross-hybridization or by the use of PCR.

### 17.3.2 DNA Tumor Viruses

Many DNA viruses—of the adenovirus, herpesvirus, poxvirus and papovavirus families—also encode oncoproteins; however, the transforming genes rarely have proto-oncogene homologs within the normal genome. In general, while the RNA tumor viruses promote tumor development by harboring or generating oncogenic alleles, several of the DNA tumor viruses, such as the simian type 40 virus (*SV40*), human papillomaviruses and adenoviruses, primarily contribute to tumorigenesis by inactivating or inhibiting the activities of tumor suppressor proteins. Several of the specific interactions of the DNA tumor virus proteins with tumor suppressor proteins are addressed below in detail in the discussion of TSG products.

## 17.4 ONCOGENIC ALLELES IN HUMAN CANCERS

The precise location of oncogenic mutations often provided the first indication of the locations of important functional domains of the protein. Genetic, biochemical and cellular studies in both humans and model organisms have further illuminated the functions of these genes. The majority of proto-oncogenes are now known to be the components of signal transduction pathways, which are responsible for translating extracellular signals into nuclear changes in gene expression. Activation of proto-oncogenes (and inactivation of TSGs) results in the deregulation of these pathways, such that the aspects of cellular behavior—for example, proliferation and survival—become autonomous. Proto-oncogenes have been discovered at most stages of the signal transduction pathways, acting as (among others) ligands, receptors, membrane-associated tyrosine kinases, lipid kinases, cytoplasmic regulators, G proteins, kinases, transcription factors and transcriptional coactivators. A small subset of proto-oncogenes is more directly involved in cellular proliferation and survival, and functions as components of the cell cycle or anti-apoptotic machinery. For example, *CCND1* and *CDK4*, encoding cyclin D1 and cyclin dependent kinase 4 (CDK4), respectively, have both been found to be activated in tumors. The anti-apoptotic gene *Bcl-2* is another target for activation, and was first identified at the breakpoint of translocations in follicular lymphomas. An important consequence of oncogenic activation, therefore, is the uncoupling of cell proliferation and survival from regulation by extrinsic factors. This can be achieved either by constitutive activation of mitogenic signaling pathways or through direct stimulation of cell cycle progression or cellular survival.

Certain oncogenes (and also TSGs) are important in the advanced stages of tumorigenesis. A variety of

<i>pim1</i>	T-cell lymphoma	M-MLV	Mouse

proto-oncogenes are involved in the regulation of the actin cytoskeleton, cell adhesion, and extracellular matrix. Deregulation of these facets via oncogene activation promotes the cell migration and substrate independence required for tumor cell invasion and metastasis. Other oncogenes are thought to have a role in the process of angiogenesis; the induction of new blood vessel growth from the existing vessels. This process is probably essential if solid tumors are to enlarge beyond around 1 mm<sup>3</sup>.

Proto-oncogene activation probably contributes to the development of all sporadic cancers. Activating germline mutations in proto-oncogenes is likely, in general, to be lethal, but mutations in a limited number of proto-oncogenes are heritable and give rise to familial cancer syndromes. Germline mutations in *MET*, *RET* and *CDK4*, for example, are respectively responsible for hereditary papillary renal cancer, multiple endocrine neoplasia type 2 (MEN2), and some cases of familial melanoma. The majority of cancer syndromes are caused by germline mutations in TSGs, where, in contrast to proto-oncogene mutations, loss of the remaining wild-type allele is the initiating transforming event. Even here, the progression to full tumorigenicity requires further mutations in additional, probably multiple, proto-oncogenes and tumor suppressors. It should be stressed that although the study of the oncogenes carried by acute transforming retroviruses has led to the identification of many genes with critical roles in cell growth, only a subset of these genes is frequently affected by somatic mutations in human cancer and, as mentioned previously, most of these occur as somatic rather than germline mutations. In addition, as

reviewed below, several oncogenes that are frequently activated in human cancer involve gene sequences that are not known to be harbored by acute transforming viruses. Many of the oncogenic alleles often observed in human cancers are summarized in Table 17-4. A more complete list is available online at <http://www.sanger.ac.uk/genetics/CGP/Census/>.

### 17.4.1 Oncogenes Identified by DNA Transfection

DNA transfection techniques were first used to study and identify the transforming genes of RNA and DNA tumor viruses. In these assays, DNA from primary human tumors or tumor-derived cell lines is transferred into non-tumorigenic recipient cells, and cells that acquire morphologic changes and lose contact inhibition of their growth (so-called “focus formation”) are studied further (Figure 17-1). The human tumor-derived DNA sequences that are sufficient for mediating transformation can ultimately be recovered and characterized by serial passaging of DNA from a focus (Table 17-5).

In seminal studies using the DNA transfection approach, the research groups of Robert Weinberg, Jeffrey Cooper, and Michael Wigler identified the first oncogenic allele in human cancer. This oncogenic allele was a mutated *H-RAS* gene in the human bladder cancer cell line known as EJ or T24. Their observation was particularly notable because *RAS* genes had previously been identified by the characterization of the cellular homologues of the *v-onc* genes in the Harvey and Kirsten rat sarcoma viruses (*h-ras* and *k-ras*, respectively).

**TABLE 17-4 Representative Oncogenic Alleles in Human Cancers**

Gene	Activation Mechanism	Protein Properties	Tumor Type
K-RAS	Point mutation	p21 GTPase other cancers, leukemia	Pancreatic, colorectal, lung (adeno) and
N-RAS	Point mutation	p21 GTPase	Myeloid leukemia
H-RAS	Point mutation	p21 GTPase	Bladder and other cancers
<i>EGFR (ErbB-1)</i>	Amplification, rearrangement	Growth factor receptor	Gliomas, carcinomas
<i>NEU (ErbB-2)</i>	Amplification	Growth factor receptor	Breast, ovarian, and other carcinomas
<i>MYC</i>	Chromosome translocation amplification	Transcription factor	Burkitt's lymphoma; SSCL; other cancers
<i>N-MYC</i>	Amplification	Transcription factor	Neuroblastoma, SCCL
<i>L-MYC</i>	Amplification	Transcription factor	SCCL
<i>BCL2</i>	Chromosome translocation	Anti-apoptosis protein	B-cell lymphoma (follicular type)
<i>CYCD1</i>	Amplification, chromosome translocation	Cyclin D	Breast cancer, B-cell lymphoma, various carcinomas
<i>BCR-ABL</i>	Chromosome translocation	Chimeric nonreceptor tyrosine kinase	CML, ALL (T cell)
<i>RET</i>	Rearrangement	Chimeric receptor tyrosine kinase	Thyroid cancer (papillary)
<i>TRK</i>	Rearrangement	Chimeric receptor tyrosine kinase	Colorectal cancer
<i>HST</i>	Amplification	Growth factor (FGF-like)	Gastric cancer
<i>APL-RARA</i>	Chromosome translocation	Chimeric transcription factor	Acute promyelocytic leukemia
<i>E2A-PBX1</i>	Chromosome translocation	Chimeric transcription factor	Pre-B-ALL
<i>MDM2</i>	Amplification	p53 binding protein (nuclear)	Sarcomas
<i>GLI</i>	Amplification	Transcription factor	Sarcomas, gliomas
<i>CDK4</i>	Amplification	Cyclin-dependent kinase	Sarcomas, gliomas

Abbreviations: ALL, acute lymphoid leukemia; CML, chronic myeloid leukemia; SCCL, small cell lung cancer.

FIGURE 17-1

Subsequent studies established that the “activated” *H-RAS* allele in the bladder cancer cell line differed from a normal copy of the gene by a single nucleotide substitution. This nucleotide substitution, from G to T, resulted in a single amino acid change from glycine to valine at codon 12. Additional DNA transfection studies established that about 10–15% of human tumors and tumor cell lines possessed *H-RAS*, *K-RAS*, or *N-RAS* alleles with mutations. *N-RAS* is the third closely related *RAS* gene family member that was first identified as a transforming allele in a human neuroblastoma. *RAS* gene mutations are particularly prominent in several common cancer types (Downward, 2003), and the mutational spectrum and functional significance of *RAS* gene mutations in several types of cancer are addressed below.

Several other oncogenic alleles that are not members of the *RAS* gene family have also been identified by the DNA transfection approach. Moreover, several of these genes identified are not related to the *v-onc* genes of the acute transforming viruses. Among the genes identified are *NEU*, *TRK*, *RET*, *MET*, *MAS*, *HST*, and *KS3*. While the *MAS* oncogene appears to be an integral membrane protein, the others are members of the tyrosine kinase growth factor receptor family (*NEU*, *MET*, *RET*, or *TRK*) or the fibroblast growth factor family (*HST*, *KS3*). Despite the successes of the DNA transfection approach in the identification of novel oncogenic alleles in human cancer, the approach is very labor intensive and has failed to detect a number of oncogenic alleles present in human cancers, in large part because the mutant alleles failed to cause morphologic transformation of rodent fibroblasts, the recipient cells typically used in the assays. Moreover, the approach often identified mutant alleles that were generated during the in vitro manipulations of the tumor-derived DNA and did not actually exist in the cancers from which the DNA was prepared.

**17.4.1.1 The *RET* Gene and Multiple Endocrine Neoplasia Type 2.** Unlike most inherited cancer predisposition syndromes, multiple endocrine neoplasia type 2 (MEN 2) results from the activation of a proto-oncogene, *RET*, rather than the inactivation of a TSG. *RET*, which maps to 10q11.2 and comprises 21 exons spanning >60kb, encodes a transmembrane tyrosine kinase. The gene was identified by the transfection method using DNA from a human monocytic leukemia cell line and a standard NIH-3T3 transformation assay. The extracellular portion of the *RET* protein comprises a cadherin-like domain in addition to a cysteine-rich motif, while its intracellular region contains two tyrosine kinase subdomains. The protein forms part of a receptor complex whose ligands include glial cell line-derived neurotrophic factor (GDNF), neurturin, artemin and persephin (Marx, 2005). The ligand specificity is dictated by the presence in the complex of GDNF family receptor (GFR) alpha proteins 1–4 that act as co-receptors. Ligand binding by the receptor induces its dimerization and the activation of its tyrosine kinase. This, in turn, leads to its auto-phosphorylation on tyrosine residues and the subsequent activation of signaling cascades, including the *RAS*/mitogen-activated protein kinase pathway. The receptor plays an important role during the development of the kidney and the enteric nervous system with GDNF acting to promote the growth of the ureteric bud and to protect the enteric neurons from apoptotic cell death.

Germline gain-of-function mutations in *RET* are linked to three dominantly inherited related cancer predisposition syndromes: multiple endocrine neoplasia (MEN) type 2A and 2B (MEN 2A and MEN 2B) and familial medullary thyroid cancer (FMTC) (Marx, 2005). Individuals affected by FMTC simply show familial clustering of medullary thyroid cancer (MTC). In those with

TABLE 17-5 Summary of Selected Familial Cancer Syndromes						
Syndrome	Inheritance in Familial Cases	Tumor	Associated Cancers/Trails	Chromosome Location	Responsible Gene	Principal Pathogenesis
Neurofibromatosis type 1 (NF1)	AD	Neurofibromas	Neurofibrosarcoma, brain tumors	17q11	<i>NF1</i>	Negative regulation of cell growth
Hereditary non-polyposis colorectal cancer (HNPCC)	AD	Colorectal cancer	Endometrial, ovarian, hepato-biliary, and urinary tract cancer	2p16 3p21 Others	<i>MSH2</i> <i>MSH2</i> <i>Others</i>	DNA mismatch repair
<i>MutYH</i> (or <i>MYH</i> ) associated polyposis (MAP)	AR	Colorectal cancer	Intestinal polyposis	1p34.1	<i>MUTYH</i>	DNA glycosylase
Familial adenomatous polyposis (FAP)	AD	Colorectal cancer	Intestinal polyposis Duodenal tumors Desmoid tumors Jaw osteomas Medulloblastoma	5q21	<i>APC</i>	Regulation of actin
Familial breast cancer	AD	Breast cancer	Ovarian cancer (especially with <i>BRCA1</i> )	17q21 13q12 17q22	<i>BRCA1</i> <i>BRCA2</i> <i>RAD51C</i>	Double-strand break repair
Familial melanoma	AD	Melanoma	Pancreatic cancer	9p21	<i>CDKN2A</i>	Encoding a regulatory protein
von Hippel–Lindau disease	AD	Renal cell carcinoma pheochromocytoma	Retinal angiomas, cerebellar hemangioblastomas	3p25	<i>VHL</i>	Indirect regulation of cell growth
Multiple endocrine neoplasia type 1 (MEN1)	AD	Parathyroid hyperplasia Pituitary adenomas Pancreatic islet cell tumours		11q13	<i>MEN1</i>	Probable regulation of cell growth
Multiple endocrine neoplasia type 2 (MEN2)	AD	Medullary thyroid cancer Pheochromocytoma	Parathyroid hyperplasia (in MEN2A) Mucosal neuroma (in MEN 2B)	10q11	<i>RET</i> proto-oncogene	Receptor tyrosine kinase
Cowden syndrome	AD	Breast & thyroid cancer	Endometrial cancer macrocephaly, mucocutaneous lesions	10q23	<i>PTEN</i>	Lipid metabolism
Hereditary diffuse gastric cancer	AD	Diffuse gastric cancer	Possibly lobular breast cancer	16q22	<i>CDH1</i>	Calcium and regulation of cell growth
Neurofibromatosis type 2	AD	Acoustic neuromas	Meningioma, gliomas, ependymomas	22q12	<i>NF2</i>	Linker protein in cell adhesion
Li-Fraumeni syndrome	AD	Sarcomas, breast cancer	Brain tumors, leukemia, adrenocortical carcinoma, others	17q13	<i>TP53</i>	Response to cell growth
Familial retinoblastoma	AD	Retinoblastoma	Osteosarcoma	13q14	<i>RB1</i>	Transcription control

MEN 2A, however, MTCs are often accompanied by pheochromocytomas and parathyroid hyperplasia. The most severe syndrome (MEN 2B) is characterized by the features of MEN 2A in addition to ganglioneuromas of the lips, tongue, and colon. In contrast to the gain-of-function point mutations in *RET* associated with these conditions, the loss-of-function *RET* mutations cause Hirschprung's disease. Rarely, Hirschprung's disease has even occurred in families with MEN 2, but the pathogenic mechanism is not yet fully understood.

The different MEN 2 and FMTC phenotypes are associated with different spectra of predisposing *RET* mutations. Missense mutations affecting a conserved cysteine residues (Cys 609, 611, 618, 620, or 634) in the cysteine-rich region of the extracellular domain of the RET have been found, by the International *RET* Mutation Consortium, in 98% of 203 MEN 2A families and in 79% of 30 FMTC families tested. It is presumed that these cysteine residues normally form intramolecular disulfide bonds and that the mutation of such a residue leaves an unpaired cysteine, which then forms an intermolecular disulfide bond with an adjacent mutated RET molecule. It is envisaged that the resulting homodimerization of the receptor leads to constitutive receptor activation. Cysteine 634 is far more commonly mutated in MEN 2A than in FMTC. The basis of the phenotypic difference between FMTC and MEN 2A patients is not yet clear, although it may result from differing levels of receptor activation.

In contrast, the mutations found in those with MEN 2B (and in some FMTC families) occur in one of the intracellular tyrosine kinase domains (Marx, 2005). In particular, a germline mutation involving the replacement of methionine 918 by a threonine residue is found in almost all MEN 2B cases (Marx, 2005). This methionine residue is situated in the substrate recognition pocket within the catalytic core of the tyrosine kinase. Its substitution leads to altered substrate specificity, with, for example, reduced binding to GRB2, and, presumably, aberrant cellular signaling. As might be expected, MEN 2B tumors have been found to have a different gene expression pattern from those in MEN 2A (Santoro et al., 2004). The intracellular FMTC-associated mutations, at codons 768, 790, 791, 804, 844 and 891, cause receptor activation in the absence of ligand binding and dimerization.

Finally, somatic *RET* mutations are uncommon in sporadic pheochromocytoma but somatic codon 918 *RET* mutations have been detected in 25% of sporadic MTC, and germline *RET* mutations have been reported in 6–23% of apparently sporadic cases of MTC. Following the success of the small molecule inhibitor STI571 (imatinib) in targeting tyrosine kinases, testing is now underway in several possible further targeted therapies. For instance, hereditary MTCs have been reported to be highly responsive to the tyrosine kinase inhibitor, vandetanib, which

appears to have specific activity for the mutated *RET* receptor (Imyanitov and Moiseyenko, 2011).

### 17.4.2 Oncogenes Identified by the Study of Chromosomal Translocations

The nonrandom chromosomal alterations observed in cancer cells have proven particularly valuable for the identification of oncogenic alleles. In many cases, a strong correlation has been established between a particular chromosomal abnormality and the type of tumor, and even its specific histopathological subtype. Over the past two decades, standard karyotypic analyses have identified an enormous number of specific chromosomal abnormalities in leukemias and lymphomas, perhaps in large part, because these malignancies can be induced to divide in culture more readily than many solid tumors (Messahel et al., 2005) and obtaining good quality metaphase chromosome preparations is considerably easier. Nevertheless, nonrandom chromosomal aberrations are increasingly being detected in solid tumors using either standard karyotypic analysis or fluorescence in situ hybridization-based approaches, and several oncogenic alleles generated by specific chromosomal abnormalities in solid tumors have been characterized (Messahel et al., 2005).

Many of the chromosomal abnormalities in lymphomas and lymphoid leukemias involve recombination between an immunoglobulin (Ig) or T-cell receptor (TCR) locus and a novel gene. Sequence analysis of the translocation joint sequences has revealed that the canonical heptamer–nonamer sequences used by the recombinase system during normal somatic rearrangement of the *Ig* and *TCR* genes have probably generated the translocation, as a result of a recombination error. The translocation juxtaposes the gene sequences present at the chromosomal break point with a TCR or an *Ig* locus, thus altering the normal structure and/or the expression pattern of the gene(s) present near the break point. For example, a gene that is normally expressed only in neural tissues or in developing embryonic tissues may be abnormally activated. The altered gene expression consequently leads to abnormalities in the proliferation and/or differentiation of the affected cells. In addition, because many of the translocations in lymphomas or leukemias involve *Ig* or *TCR* locus sequences, the subsequent proximity of the novel gene to the well-characterized *Ig* or *TCR* locus sequences has often allowed a novel gene to be identified rapidly by standard molecular cloning approaches. Among the genes that have been found to be commonly activated in lymphoid tumors by juxtaposition with *Ig* or *TCR* locus sequences are *MYC* and *BCL2*, both of which are discussed in greater detail below. Other genes that have been found to be activated in lymphoid tumors by juxtaposition with the *Ig* and *TCR* loci are genes encoding transcription factors, such as *TTG1*, *LYL1*, and *SCL1*, and

FIGURE 17-2

those encoding cell-cycle regulatory proteins, including *PRAD1*, *BCL1*, and *CCND1*.

A number of other translocation break points that do not involve the Ig or TCR locus have also been characterized in hematopoietic malignancies. Many of these other translocations, while deregulating gene expression, also generate novel chimeric proteins by fusing gene sequences from one side of the break point with the gene sequences on the other side of the break point. The first example of such an oncogenic allele encoding a chimeric protein was provided by the elucidation of the molecular basis of the Philadelphia chromosome. The Philadelphia chromosome was first described by Nowell and Hungerford in 1960, as a result of their karyotypic analysis of bone marrow cells from a patient with chronic myelogenous leukemia (CML). Subsequent studies in the 1970s established that the Philadelphia chromosome was generated by a translocation involving chromosomes 9 and 22. The Philadelphia chromosome can be identified by cytogenetic studies in the vast majority of patients with CML, as well as in some adult and pediatric patients with lymphoid leukemia. The translocation fuses chromosome 9q sequences from the *ABL* gene, a cellular homolog of a *v-onc* gene, with sequences from chromosome 22q (Figure 17-2). The novel sequences on chromosome 22q are termed the *BCR* (for break point cluster region) gene. The resultant chimeric BCR-ABL protein retains the active protein tyrosine kinase sequences from the *ABL* gene, but replaces the *ABL* regulatory sequences with *BCR* sequences. The net result is the generation of a protein kinase with altered structure and function.

**17.4.2.1 Imatinib Mesylate.** One of the most exciting developments in medicine in recent years has been the development of the clinically effective selective tyrosine kinase inhibitor, imatinib mesylate (Gleevec or STI-571, Novartis Pharmaceuticals). It has revolutionized the treatment of CML through its ability to inhibit BCR-ABL, inducing remissions with almost complete elimination of the signs and symptoms (Hehlmann et al., 2005). It was probably the first neoplasia for which the elucidation of the genotype led to the rational design of a targeted therapy and it now serves as a model for the development of molecularly targeted therapies. The drug may not, however, be able to eradicate leukemic

stem cells and resistance to imatinib can eventually arise through mutations in the *ABL* kinase domain (Komarova and Wodarz, 2005; Michor et al., 2005). On account of its ability to inhibit another tyrosine kinase, C-KIT, imatinib is also effective as a therapy for metastatic gastrointestinal stromal tumors (GISTs), which are generally difficult to treat with conventional chemotherapy (Chen et al., 2005). The recent review of targeted therapies by Stegmeier et al. describes the current uses of imatinib and discusses the importance of precise dosage in effecting optimal responses in treating CML and GIST (Stegmeier et al., 2011). In addition, the importance of molecular drug transporters in relation to the effectiveness of imatinib has now been determined (Eechoute et al., 2011). The success of imatinib and the subsequent generations of the constitutively activated *ABL* kinase have paved way for the development of several further small molecule inhibitors of mutated gene products. These include inhibitors of mutated *EGFR*, *ERBB2*, *KIT*, *PDGFRA*, *PML-RARA*, *MET*, and *ALK*, which are either in clinical trials or are already in clinical use (Stratton, 2011).

### 17.4.3 Oncogenes Identified by DNA Amplification

Several oncogenic alleles have been identified because they are contained within DNA sequences that become sequentially (tandem) repeated or amplified in tumor cells. In some cases, the amplified DNA sequences were first revealed in karyotypic analyses as extrachromosomal elements termed *double minute chromosomes* (DMs) or as novel banding regions on chromosomes termed *homogeneously staining regions* (HSRs). DMs and HSRs contain from 20 to several hundred copies of a chromosomal region of several hundred thousand base pairs. Biological selection for the generation and maintenance of the amplified DNA sequences in the tumor cells is thought to be driven by the increased copy number and increased expression of a target gene or genes within the larger region of the amplified DNA. Further detailed molecular genetic characterization of the amplified sequences is necessary to identify the specific target(s) genes in the larger region of the amplified DNA. In some

cases, a cellular homolog of a known *v-onc* gene is thought to be the target gene present in the amplified DNA. In other cases, characterization of the amplified DNA sequences has led to the identification of novel oncogenic alleles.

Among the cellular homologs of *v-onc* genes affected by DNA amplification in human tumors are the *MYC*, *MYB*, epidermal growth factor receptor (*EGFR*), and *ERBB2* (also known as *HER2* or *NEU*) genes. The *MYC* and *MYB* genes encode transcription factors, and the *EGFR* and *ERBB2* genes encode transmembrane receptor tyrosine kinase proteins. Other novel cellular proto-oncogenes that have been identified because they are present within the amplified DNA sequences include two genes, *N-MYC* and *L-MYC*, that are closely related to *MYC*, the *GLI* gene, the *MDM2* gene (see the *p53* tumor suppressor gene section), the *cyclin D1/PRAD1* gene (also activated by chromosomal translocation as noted above), and several genes encoding growth factors (e.g. *HST*, *INT2*). Because the DNA amplifications involve several hundred thousand base pairs, in some tumors more than one cellular proto-oncogene may be contained in the amplified sequences. One example of DNA amplifications affecting several proto-oncogenes is the amplification of chromosome 12q sequences in a subset of sarcomas. These amplifications often involve and activate the expression of the *MDM2*, *GLI*, and *CDK4* (see the section on p105-RB function below) genes.

Many candidate oncogenes have been identified by comparative genome hybridization and by studying changes in global gene expression in human solid tumors. Additionally, candidate oncogenes have been found to be amplified in certain tumor types. For example, telomerase activity has been linked to cellular immortality and tumor progression and is a potential target for chemotherapy. The human telomerase RNA gene (*hTERC*) was mapped to chromosome 3q26.2–q27, a region frequently subject to copy number gains in human tumors. Moreover, mutations in *hTERC* are associated with the rare, autosomal dominant form of dyskeratosis congenita, while the most common, X-linked, form is associated with mutations in the *DKC1* gene, encoding DYSKERIN, another protein closely involved in telomerase function (Bessler et al., 2004; Marrone et al., 2005).

#### 17.4.4 Oncogenes Identified by DNA Sequencing

A major program of cancer genome sequencing is currently underway at the Wellcome Trust Sanger Institute in Cambridge, United Kingdom, and elsewhere worldwide. The objective is to sequence the genomes of thousands of individual cancers. The data have revealed that these genomes usually contain between 1000 and 10,000 somatically acquired mutations (Stratton, 2011). The systematic sequencing of cancer genomes has led to

the discovery of new proto-oncogenes, including *IDH1*, which encodes isocitrate dehydrogenase 1 (a Krebs cycle component), *EZH2*, *JAK2* and *FOXL2* (encoding a tissue-specific transcription factor) and *BRAF* (Stratton, 2011). Somatic mutations in *BRAF* (which encodes a serine–threonine kinase) are particularly frequent, occurring in 50–70% of malignant melanomas, 10–15% of CRCs and in 50% of papillary thyroid cancers and one specific mutation V600E is especially common, facilitating molecularly targeted drug development. In fact, since the identification of *BRAF* as a mutated cancer gene in an early cancer genome sequencing screen in 2002, orally available small molecule inhibitors have been developed and tested in clinical trials and the mechanisms of emerging drug resistance have even been identified. The current catalog of identified cancer genes can be viewed at the Cancer Genome website (<http://www.sanger.ac.uk/genetics/CGP/Census/>) and shows that more than 1% of human genes are mutated in cancer (mostly somatically but 20% of these contain germline mutations).

### 17.5 TUMOR SUPPRESSOR GENES

As reviewed above, the identification of oncogenic alleles in human tumors has been facilitated by the prior identification of the *v-onc* genes, the characterization of sequences present at translocation break points, and the ability of the oncogenes to generate tumorigenic growth properties when transferred to nontumorigenic recipient cells. In contrast, the direct identification of TSGs has proven far more difficult because functional strategies for their identification have a number of practical problems. For example, although the successful transfer of a TSG to a tumor cell would be expected to suppress at least some of the altered growth properties of the tumor cell, such as anchorage-independent growth, lack of contact inhibition, unlimited life span, and tumorigenicity, the identification of suppressed cells in a background of fully transformed cells has proven to be a particularly difficult experimental task. Thus, the strategies to identify TSGs and the specific alterations in these genes in human cancers have been, by necessity, more circuitous.

#### 17.5.1 Historical Evidence for the Existence of Tumor Suppressor Genes

The studies of Henry Harris and his colleagues in 1988 formed the basis of the concept that the ability of cells to generate a tumor is a recessive trait, resulting, at least in part, from the inactivation of a class of cellular genes termed TSGs. These investigators first established that hybrids generated from the fusion of fully malignant murine tumor cells with nontumorigenic murine cells were often nontumorigenic when injected into mice. The hybrid cells, however, often reverted to tumorigenicity when passaged in culture, and the tumorigenic revertants

had chromosome losses detected when compared to the nontumorigenic hybrids. The interpretation of Harris and his colleagues, that is, that malignancy could be suppressed in somatic cell hybrids between tumorigenic and nontumorigenic cells, subsequently received support from many additional studies of somatic cell hybrids generated from the fusion of normal and tumorigenic rodent cells, as well as normal and malignant human cells. Hybrids retaining both sets of parental chromosomes were suppressed, with tumorigenic segregants arising most commonly after the loss of specific chromosomes from the normal parent. Moreover, it was found that tumorigenicity could be suppressed even if activated oncogenes, such as mutated *RAS* genes, were expressed in the hybrids.

The observation that the reversion to malignancy of the hybrids was associated with the loss of specific chromosomes contributed by the nontumorigenic cells suggested that specific chromosomes might be sufficient for suppression of tumorigenicity. Furthermore, the findings suggested that tumors must arise, in part, through the inactivation of a class of cellular genes termed TSGs. Evidence supporting the proposal that specific TSGs might be sufficient for the suppression of the tumorigenic phenotype was initially provided by studies in which single chromosomes were transferred using a technique known as microcell-mediated chromosome transfer. For example, the tumorigenicity of some cervical cancer cells or rhabdomyosarcoma cells was shown to be suppressed following transfer of human chromosome 11. There was a degree of cell-type specificity in relation to the ability of a particular chromosome to suppress tumorigenicity because chromosome 11 failed to suppress the tumorigenicity of some neuroblastoma and renal cell cancer cells. Furthermore, although the ability of the cells to form tumors in immunocompromised (“nude”) mice and to grow in an anchorage-independent fashion could be suppressed following single-chromosome transfer, other traits characteristic of the parental tumor cells (e.g. unlimited life span in culture) were still retained in the suppressed hybrids. The observation that not all properties of the parental tumor cells could be suppressed by a single chromosome (and perhaps a single TSG), however, is clearly consistent with the proposal that tumors arise as a result of multiple genetic alterations.

While the somatic cell genetic studies of tumorigenesis reviewed above did not lead directly to the identification of TSGs, they did provide persuasive evidence that a subset of the mutations in human cancers must be in genes of this type. In addition, concurrent with the initial cell fusion experiments of Harris and his colleagues, other epidemiological and genetic studies also suggested an important role for the inactivation of cellular genes in cancer development. Many of these studies were first carried out on retinoblastoma, and some of the critical observations from these studies are reviewed below.

## 17.5.2 The Retinoblastoma Gene

**17.5.2.1 Retinoblastoma: A Paradigm for Tumor Suppressor Gene Identification.** The relative rarity of retinoblastoma belies the importance of observations gleaned through the study of this tumor. Indeed, many of the concepts and techniques used to identify and characterize TSGs and inherited and somatic genetic alterations in cancer were first established through the studies of the genetic basis of retinoblastoma. As is true of a number of cancer genes, however, the precise functions of the protein that the underlying gene encodes are currently still being elucidated (see below).

Retinoblastoma is a pediatric tumor that occurs sporadically in many patients but also occurs in some families in a pattern consistent with autosomal dominant inheritance. Knudson’s analysis of the age-specific incidence of retinoblastoma led him to propose that two distinct mutagenic events were necessary for the development of retinoblastoma in all patients. Knudson’s hypothesis is thus often termed “the two-hit hypothesis.” He proposed that in those patients with the inherited form of the disease, one mutation was present in the germline and in all cells of the body. A second mutational event occurring in any one of the developing retinoblasts would then lead to the generation of a retinoblastoma. Thus, in a patient with the inherited form of the disease, one or more retinoblastomas might likely develop; however, the number of retinoblastomas arising in an inherited case might well be expected to vary from none to three or four, depending on the frequency of second mutations. With this model, Knudson could account for the absence of disease in some patients known to harbor the predisposing mutation (i.e. skipped generations), as well as the presence of bilateral or multifocal disease in some affected family members. In those with the sporadic form of retinoblastoma, Knudson proposed that both the mutational events were somatic and arose in the same developing retinoblast. The least probability that the two somatic mutations would occur in the same retinoblast was consistent with the low prevalence of retinoblastoma in the general population. Although each of the two mutational events could have been predicted to affect different genes, Knudson subsequently proposed that the two mutational events affect the two parental copies of a retinoblastoma TSG (subsequently referred to here as the *RB1* gene). Thus, while retinoblastoma could be inherited as a dominant trait at the phenotypic level, at the cellular level, mutations in the *RB1* gene were predicted to be recessive, such that both parental copies of the gene would need to be inactivated in a cell for a retinoblastoma to develop.

The significance of Knudson’s hypothesis should not be underestimated. The two-hit hypothesis not only served as a framework for considering the mechanisms through which inherited and somatic genetic mutations might interact in tumor development, but it also linked

the notion of recessive genetic determinants for human cancer development to the somatic cell genetic observations demonstrating that the ability to form tumors is often a recessive trait.

Cytogenetic studies of peripheral blood lymphocytes from retinoblastoma patients provided the first clues to the location of the retinoblastoma predisposition gene. In about 5% of patients with retinoblastoma, interstitial deletions involving band q14 of chromosome 13 were identified in peripheral blood lymphocytes or normal skin fibroblasts. It was thus hypothesized that a gene predisposing to retinoblastoma development must reside at 13q14. Subsequent studies noted that the levels of esterase D, an enzyme of unknown physiological function, were reduced in normal cells from some patients with germline chromosomal deletions involving 13q14, as compared to karyotypically normal family members. Therefore, in at least a subset of patients with deletions of chromosome band 13q14, the deletions were likely to affect not only one copy of the *RB1* gene but also the esterase D gene and perhaps several other genes.

Further examination of the esterase D locus in those with retinoblastoma yielded several other critical insights into the genetics of retinoblastoma. Analysis of the segregation patterns of polymorphic esterase D isozymes in several retinoblastoma kindreds in which the affected members lacked cytogenetic alterations of 13q14 provided strong evidence for genetic linkage between the esterase D locus and the retinoblastoma predisposition gene. In addition, studies of esterase D proved particularly illustrative in a child with inherited retinoblastoma who had no detectable cytogenetic alteration in her normal cells. Though a cytogenetic alteration was not apparent, this child was noted to have an ~50% reduction of esterase D levels in peripheral blood cells. Of even greater interest, tumor cells from this patient had no detectable esterase D activity, despite having one copy of chromosome 13. Based on these observations, Benedict, Sparkes, and their colleagues proposed that in all cells of the patient, one copy of chromosome 13 was affected by a submicroscopic deletion. This submicroscopic deletion inactivated one copy of the *RB1* gene and one copy of the esterase D gene. During tumor development, the normal copy of chromosome 13 was lost, leaving only the defective chromosome 13 in the tumor cells. Based on their findings in this patient, these investigators concluded that the predisposing mutation in the patient, the submicroscopic 13q deletion involving the *RB1* gene and the esterase D gene, was recessive at the cellular level. The effect of the predisposing mutation could be observed, however, by the inactivation of the remaining normal copy of the *RB1* gene, such as by its loss in the tumor cells. These studies thus provided the first direct experimental evidence supporting Knudson's two-hit hypothesis for retinoblastoma development.

To establish the generality of this two-hit model for retinoblastoma, Cavenee, White, and their colleagues undertook the studies of additional cases of inherited retinoblastoma as well as sporadic cases, using DNA probes from chromosome 13. The probes detected DNA sequence polymorphisms and thus allowed the two parental copies of chromosome 13 to be distinguished from one another in normal and tumor tissues from each patient. Following the comparison of the parental alleles present in the paired normal and tumor samples from each patient, Cavenee et al. demonstrated that the loss of heterozygosity (LOH, also termed allelic loss; i.e. the loss of one parental chromosome) for chromosome 13 had occurred during the development of more than 60% of retinoblastomas studied. They also demonstrated that LOH could occur by a number of different mechanisms (Figure 17-3). The unmasking of the recessive predisposing mutations at the retinoblastoma locus, whether the mutation had been inherited or had arisen somatically, occurred through the same chromosomal mechanisms. Furthermore, the study of inherited cases confirmed that the chromosome 13 homolog retained in tumor cells that had suffered chromosome 13 LOH was always derived from the affected parent.

Previous epidemiological studies had established that patients with the inherited form of retinoblastoma were also predisposed to the development of osteosarcomas, with these lesions most often arising in areas that had been exposed to radiotherapy. Study of chromosome 13q LOH in osteosarcomas arising in patients with retinoblastoma, as well as in apparently sporadic cases of osteosarcoma, revealed that the majority of osteosarcomas studied had undergone LOH for the 13q region containing the *RB1* gene. Such findings established a genetic link between retinoblastoma and osteosarcoma.

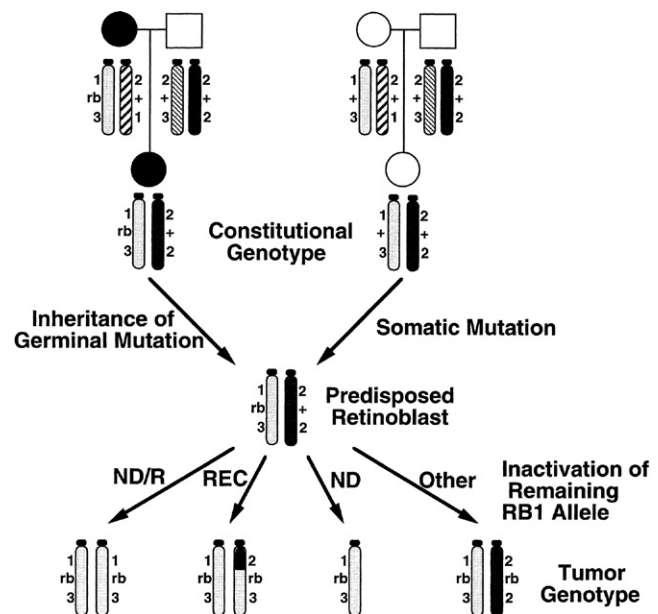

FIGURE 17-3

The studies of chromosome 13q LOH in retinoblastomas and osteosarcomas were therefore particularly instructive. They provided definitive evidence in support of Knudson's hypothesis and illustrated the multiple chromosomal mechanisms that could unmask the pre-existing recessive mutations at a tumor suppressor locus. The studies also established that similar genetic mechanisms could account for both inherited and sporadic cases of a particular type of cancer. Finally, the DNA-based studies provided genetic evidence that inactivation of the same TSG was responsible, at least in part, for the development of two distinct tumor types.

**17.5.2.2 Molecular Cloning and Mutational Analysis of the Retinoblastoma Gene.** The molecular cloning of the *RB1* gene was greatly facilitated by the identification of a chromosome 13q14 DNA marker that detected rearrangements in Southern blot analysis of two retinoblastomas and the complete loss of both retinoblastoma alleles in a third case. Following its identification, it was established that *RB1* is a large gene with 27 exons, spanning more than 200 kb of genomic DNA. The penetrance of *RB1* germline mutations is high and it has been estimated that 90% of individuals with a germline *RB1* mutation would develop retinoblastoma.

The cloning of the *RB1* gene allowed definitive studies of the inherited and somatic mutations present in the gene. Although gross deletions, of either inherited or somatic origin, affect the *RB1* gene in a subset of retinoblastomas and osteosarcomas, most of these tumors do not have gross alterations of the gene. In fact, most mutations inactivating the *RB1* gene are point mutations or small insertions and deletions that result in premature truncation of the protein product. Several missense and splicing mutations have also been identified in primary retinoblastomas and osteosarcomas. Almost all *RB1* tumorigenic mutations result in the disruption or loss of the "pocket" domain of the retinoblastoma protein (pRB) that is required for interaction with E2F protein and viral oncoproteins (see below). In general, no clear genotype–phenotype association has yet emerged. As predicted by Knudson's hypothesis and the studies of 13q LOH, both *RB1* alleles are inactivated in retinoblastomas and osteosarcomas.

In addition to the identification of germline and somatic mutations that inactivate the *RB1* gene in retinoblastomas and osteosarcomas, functional evidence indicates that the *RB1* gene can suppress aspects of the tumorigenic phenotype when a cloned copy is introduced into retinoblastoma or osteosarcoma cells growing in culture. At least in some cases, successful transfer of a normal copy of the *RB1* gene to retinoblastoma or osteosarcoma cells results in changes in cell morphology and the suppression of growth in culture or in nude (immunocompromised) mice. In fact, there is evidence that *RB1*, which is often regarded as a prototypical tumor suppressor, can regulate not only cellular proliferation but also differentiation (Nguyen and McCance, 2005).

Since its initial cloning in 1986, *RB1* mutations have been extensively analyzed in many tumor types other than retinoblastoma and osteosarcoma. Some of these studies were motivated by observations that 13q LOH was prevalent in other tumor types. The mutations inactivating the *RB1* gene in other tumor types are similar to those in retinoblastomas and osteosarcomas and include frameshift and nonsense mutations that result in a truncated and often unstable protein; however, the prevalence of mutations in the *RB1* gene varies markedly from one tumor type to another. For example, *RB1* mutations have been observed in nearly 100% of small cell carcinomas of the lung and in about 10–20% of breast, bladder, pancreatic, and prostate carcinomas, while less than 5% of primary colorectal carcinomas contain *RB1* mutations.

Inactivation of the pRB protein in tumors can also occur indirectly, by altered expression or activity of its upstream regulators (see below), such as p16/INK4A in melanomas and pancreatic carcinomas and CDK4 in glioblastomas (Liu et al., 2004a, 2004b).

At least at first glance, the identification of somatic *RB1* mutations in tumor types other than retinoblastoma and osteosarcoma is somewhat puzzling. Patients with germline mutations in the *RB1* gene are at significantly elevated risk (relative to the general population) of developing a rather limited spectrum of tumors, including retinoblastoma, osteosarcoma, and occasionally soft tissue sarcoma and melanoma. Patients with germline mutations in the *RB1* gene do not, however, appear to be at elevated risk of the development of other tumor types in which somatic *RB1* mutations are relatively common. Given that the *RB1* gene is ubiquitously expressed in adult tissues and that its inactivation apparently contributes to the development of a number of common human cancer types, it is not yet clear why those individuals possessing germline *RB1* mutations are not predisposed to a greater variety of cancer types. Nevertheless, the data suggest that in some cell types, such as retinoblasts, the *RB1* gene is one of the primary controlling elements in growth regulation, while in other cell types, such as mammary and prostatic epithelial cells, the growth regulatory pathways in which the *RB1* gene plays a role may be more redundant.

The cloning of the *RB1* gene ushered in a new era in the management of patients and families with inherited cancer syndromes. Those individuals who carried germline mutations could now be identified and closely followed, while those who had not inherited a specific *RB1* mutation possessed by a parent could be spared anxiety and frequent clinical examinations.

**17.5.2.3 Function of the Retinoblastoma Protein.** The protein product of the *RB1* gene, pRB (also termed RB or p105-RB), is a nuclear phosphoprotein of 928 amino acids residues with a molecular mass of about 105–110 kDa. The first critical insights into the function of pRB were provided by the studies of Ed Harlow

and his colleagues in 1988. They demonstrated that the E1A oncoprotein of the murine DNA tumor virus adenovirus type 5 complexed with pRB. Prior studies had established that E1A had many functions, including cell immortalization, induction of DNA synthesis, cooperation with other oncoproteins in transformation, and regulation of viral and host gene transcription. The studies of the Harlow group suggested that the complexing of E1A with pRB might account for some of E1A's effects on cells. Furthermore, they provided compelling evidence that the binding of E1A to pRB not only was physiologically significant but was absolutely critical to E1A's ability to mediate neoplastic transformation. In particular, they demonstrated that mutant E1A proteins that were unable to bind pRB were also unable to transform cells.

The significance of this physical interaction between a TSG product and a DNA tumor virus oncogene product was reinforced by the subsequent demonstration that several other DNA tumor virus proteins could bind to pRB, including simian virus type 40 (SV40), large T antigen and the E7 protein of human papillomavirus (HPV) type 16 (Figure 17-4). Mutations that inactivated the transforming activities of these proteins were found to inactivate their ability to complex with pRB. In addition, while HPV E7 proteins from the “high-risk” viruses (i.e. those strongly associated with cancer development), such as HPV types 16 and 18, were shown to complex tightly with pRB, HPV E7 proteins from “low-risk” viruses (e.g. HPV types 6 and 11) showed reduced binding to pRB. It is now recognized that these viral proteins interact, via their LXCXE motif, with the so-called “pocket” domain of pRB, the 3-D structure of which has now been solved.

Although the DNA tumor virus proteins inactivate the function of pRB by directly complexing with it, pRB is physiologically inactivated by protein phosphorylation during the normal progression through the cell cycle. Indeed, pRB appears to exist in a predominantly unphosphorylated or hypophosphorylated state in the G1 phase of the cell cycle and maximally phosphorylated in G2 (Figure 17-5). The critical phosphorylation events regulating the function of pRB are mediated, at the boundary between the G1 and S (DNA synthesis) phases of the cell cycle, by protein complexes that consist of a cyclin (especially cyclins D1 and E) and also a cyclin-dependent kinase (CDK). There are 16 potential CDK phosphorylation sites on pRB, and it appears that different cyclin/CDK complexes phosphorylate distinct subsets of sites, possibly in response to different growth factor signaling pathways. These phosphorylation events at the G1-S boundary reduce the ability of pRB to bind to certain cellular proteins, including members of a family of at least eight transcriptional regulatory proteins known as the E2F proteins (Tsantoulis and Gorgoulis, 2005). When it is not phosphorylated, pRB complexes with the E2F protein and prevents it from activating gene expression,

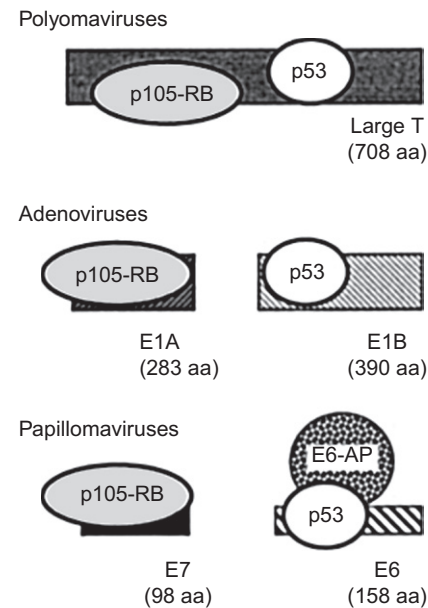

FIGURE 17-4

FIGURE 17-5

although the latter may remain bound to the promoter of its target gene. This inhibition of E2F-mediated transcriptional activation is not simply due to masking by pRB of the activation domain of E2F. Rather, pRB, bound to E2F, shuts off transcription in an active way by recruiting a histone deacetylase (HDAC1) protein (Sherr, 2004), leading to local changes in chromatin structure that result in the transcriptional repression of the gene to which the E2F protein is bound (Tsantoulis and Gorgoulis, 2005).

The transcriptional repressor complex of E2F–pRB–HDAC is believed to be disrupted by binding of a viral oncoprotein to pRB, mutation of pRB, or, physiologically, by the phosphorylation of pRB. In the resulting nonrepressed state, the E2F protein, heterodimerized with one of at least two members of the DP protein family, can activate the expression of its target genes (Figure 17-5). Further support for the role of pRB in

regulating transcription through chromatin remodeling has been provided by the detection of complexes containing pRB together with HDAC and the nucleosome disrupting proteins, hSWI/SNF. The *E2F* target genes include a number of genes that are likely to play a critical role in the cell's transition into S phase, including DNA polymerase alpha, thymidine kinase, dihydrofolate reductase and alternative reading frame (ARF). In fact, it may be the increased expression of the latter and the consequent stabilization of p53 protein (Harris and Levine, 2005) (see below), which causes the apoptosis that normally follows the phosphorylation of pRB.

Increasing evidence suggests that pRB may also bind to other cellular proteins. For instance, the C-domain of pRB, located at the C-terminal to the pocket domain, binds to C-ABL (the function of which it inhibits) and to MDM2. In fact, given that MDM2 is a critical regulator of *TP53* (see below) and that a trimeric complex of pRB–MDM2–p53 has been detected, it is likely that pRB and *TP53* act together in regulating apoptosis. In addition, pRB binds to and inhibits TAF250 kinase, a component of the important TFIID transcription factor complex, and this interaction may contribute to the transcriptional repression by pRB discussed above. Phosphorylation of the A-domain within the pocket region of pRB blocks its interaction with many proteins, including the E2F1, E2F2, E2F3 and BRG1 proteins, while the phosphorylation of the C-terminus of pRB blocks the interaction with HDAC (Cobrinik, 2005).

In addition to the repression of the expression of E2F-regulated genes, it now appears that pRB plays an important role in genomic stability (Amato et al., 2009; Manning et al., 2009; Coschi et al., 2009). In particular, loss of pRB function can cause different types of genomic change. These include changes in ploidy at the chromosomal and the subchromosomal levels. For instance, pRB inactivation leads to local amplifications, chromosome arm gains and losses and even an increased frequency of whole chromosome missegregation with losses or gains of whole chromosomes (chromosome instability or CIN). The latter is thought to result from abnormalities in the mechanism by which chromosome segregation takes place or is regulated. Such abnormalities include so-called merotelic kinetochore attachments; that is, the interaction of microtubules from both spindle poles to a single kinetochore. Currently, however, pRB inactivation appears to play a predominantly indirect role by, for instance, blocking the normal recruitment and the localization of CAP-D3/condensin II and cohesin (Manning et al., 2009; Manning and Dyson, 2011).

**17.5.2.4 Other Pocket Proteins.** Several other nuclear phosphoproteins with important roles in growth regulation share significant similarity with the retinoblastoma protein: In particular, the proteins known as p107 and p130, which, together with pRB, are known as the “pocket proteins.” These pRB-related proteins may possess physiological functions that are closely related to

those of pRB and have, in fact, also been found to complex with the E1A, SV40 large T antigen, and HPV E7 DNA tumor virus proteins. In addition, p107 has been found to substitute partly for pRB in the negative regulation of E2F1–E2F3 (Cobrinik, 2005). All three pocket proteins can regulate cell cycle progression and induce cell cycle arrest in G1 when they are overexpressed (Tsantoulis and Gorgoulis, 2005). There seems to be a certain degree of redundancy, however, between p107 and p130. In addition, mice deficient in either p107 or p130 develop normally while mice deficient in pRB die as embryos. Thus, these two pocket proteins are not yet fully regarded as classical tumor suppressors (Tsantoulis and Gorgoulis, 2005).

### 17.5.3 The *TP53* Tumor Suppressor Gene

The p53 protein was first identified in the late 1970s because it formed a tight complex with the SV40 large T antigen. It was named p53 because it is a phosphoprotein with a relative molecular mass of about 53,000 Da. Subsequent studies established that the p53 protein formed complexes with other polyomavirus large T antigens and the adenovirus E1B oncoprotein (Figure 17-4). While the p53 protein was present in small amounts in normal cells and was metabolically labile, high levels of p53 protein were present in many tumors and tumor cell lines. In addition, transfection of *TP53* expression constructs was shown to immortalize some cells. Furthermore, *TP53* appeared to cooperate with some oncogenes, such as mutated *H-RAS*, to transform primary rat embryonic fibroblasts cells to immortal, tumorigenic cells. The initial interpretation of these observations was that p53 functioned in a positive fashion to participate in tumorigenesis and that *TP53* appeared to be an oncogene.

Many subsequent studies, however, indicated that *TP53* was a TSG rather than an oncogene. For example, in Friend virus-induced mouse erythroleukaemias, the *TP53* gene was found to be a frequent target site for viral integration, and many of the integration events led to *TP53* inactivation. Rearrangements and deletions that appeared to completely inactivate *TP53* were also observed in the HL60 human promyelocytic leukemia line and in several human osteosarcomas. Furthermore, reexamination of the cellular transformation studies revealed that the cloned murine *TP53* genes used in the transformation assays were not wild type, but contained point mutations in their coding sequences. Both the wild-type murine and human *TP53* genes were shown to be incapable of mediating transformation in collaboration with *RAS* oncogenes, and the wild-type *TP53* gene was found to inhibit the transforming ability of mutated *TP53* and other oncogenes. Moreover, it was realized that the p53 protein that was found to be abnormally abundant in many tumors was usually transcriptionally inactive.

**17.5.3.1 Inactivation of the *TP53* Gene in Human Cancer.** Evidence that the *TP53* gene might be frequently inactivated in human cancers was initially provided by studies demonstrating that the LOH for chromosome 17p alleles was common in a number of tumor types, particularly CRC. Because the *TP53* gene was contained in the 17p region frequently affected by LOH, sequence analysis of the *TP53* alleles retained in colorectal tumors with 17p LOH was carried out. This analysis identified point mutations in the great majority of cases. Subsequent analysis of other tumor types with 17p LOH, including breast, lung, bladder, and brain tumors also revealed frequent mutations in the *TP53* coding region.

Mutations in *TP53* are now recognized to be very prevalent in a wide spectrum of human cancers. Indeed, *TP53* is believed to be one of the most commonly mutated genes in human cancer and loss of functional *TP53* occurs in over 50% of human tumors. The overwhelming majority of the mutations identified are located in the central region of the *TP53* coding sequences and result in the synthesis of a p53 protein with a missense substitution that usually abrogates p53's DNA-binding activity (Figure 17-6). Although *TP53* is inactivated in around 50% of human cancers by somatic mutations, in a further 20% of cancers the function of p53 is inactivated by other mechanisms. For example, in cervical cancers, the main known risk factor is the infection with the so-called "high-risk" or cancer-associated HPVs (i.e. HPV types 16 and 18). The E6 proteins encoded by the high-risk HPVs bind a cellular protein called E6-AP (for E6-associated protein). The resulting complex binds p53 and mediates its degradation via the ubiquitin pathway (Hengstermann et al., 2005) (Figure 17-4). Cancer-associated HPVs are present in the vast majority of cervical cancers, and only a small subset of cervical cancers has somatic *TP53* mutations. In the rare instances when a cancer-associated HPV E6 protein and a cellular *TP53* mutation are both present, the cancers may behave more aggressively.

In a subset of soft tissue sarcomas, a cellular protein known as MDM2 is overexpressed as a result of gene amplification involving sequences on chromosome 12q. When expressed at high levels, the *MDM2* gene functions as an oncogene. It is now well established that the MDM2 protein can bind to and inactivate the p53 protein and that MDM2 is a key physiological regulator of p53. It achieves this by masking p53's transactivation domain, and also by ensuring that p53 is a short-lived protein. MDM2 accomplishes the former by interacting with p53's N-terminus and the latter by acting as an E3 ubiquitin ligase, thus promoting p53's destruction in the proteasome. Responses of p53 in vivo are believed generally to require the stabilization of the protein, principally through reduced MDM2 binding. This occurs, for example, following (a) phosphorylation of serine 15 or serine 20 in the N terminus of p53 following the activation of the checkpoint kinase CHK2, DNA-dependent protein kinase (DNA-PK) and ataxia-telangiectasia mutated (ATM) in response to DNA damage (e.g. by gamma irradiation); or (b) transcriptional activation of p14/19ARF caused by oncogene activation. It is by binding via its amino terminus to MDM2, that p14/19ARF, (which is encoded by an ARF) at the same locus as the p16INK4A CDK inhibitor, prevents MDM2 from inducing degradation of p53. In addition to the stabilization of the protein, full activation of p53 appears to require the acetylation of lysine residues 320 and 382 at its C terminus by PCAF and p300, respectively.

**17.5.3.2 Li-Fraumeni Syndrome.** Li-Fraumeni syndrome (LFS) is a rare autosomal dominantly inherited and highly penetrant condition with a predisposition to breast and brain tumors, soft tissue sarcomas, osteosarcomas, adrenocortical carcinomas and leukemia. In addition to the somatic mutations of the *TP53* gene in a variety of different tumor types, inherited *TP53* gene mutations have been identified in 60–77% of individuals with LFS (as strictly defined) and in 20–40% of patients

FIGURE 17-6

with Li–Fraumeni-like syndrome (Varley, 2003; Barlow et al., 2004), as well as in a subset of pediatric patients with tumors such as osteosarcomas, who do not meet more strict criteria for LFS. A high proportion of children with adrenocortical carcinomas, in particular, possess germline mutations in *TP53* (Varley, 2003). LFS has been strictly defined as a proband with any childhood tumor, or a sarcoma, brain tumor, or adrenocortical tumor in those aged under 45, plus a first- or second-degree relative in the same lineage with a typical LFS tumor at any age and also an additional first- or second-degree relative in the same lineage with any cancer under the age of 60 years.

The best method for screening patients in LFS families or those with germline *TP53* mutations is still uncertain, but may include MRI for women at risk of breast cancer and abdominal ultrasound for children. In view of the radiation sensitivity of *TP53* mutant cells, radiotherapy should be avoided if possible (Varley, 2003). Given the ubiquitous expression of *TP53* in adult tissues, the basis of the tissue specificity of *TP53*-related tumorigenesis remains to be elucidated. It does not simply correspond to those tumor types in which somatic mutations are common. Mutations located within the central core (DNA-binding) domain of the gene tend to be associated with a gain of function and, unlike many TSGs, do not require a subsequent inactivation of the wild-type allele for tumorigenesis (Varley, 2003). This dominant-negative effect may result from the ability of the p53 protein monomers to bind to other similar proteins, forming homotetramers. In LFS families possessing wild-type *TP53* genes, heterozygous germline mutations have, albeit rarely, been found in the *CHK2* gene (Barlow et al., 2004) but several other candidate LFS genes have now been excluded, including *MDM2*, *PTEN*, *CDKN2A*, *BCL10*, *CHK1*, *TP63* and *BAX* (Barlow et al., 2004; Varley, 2003).

**17.5.3.3 *TP53* Function.** The p53 nuclear phosphoprotein functions primarily in transcriptional regulation, though it may also have other functions (Yee and Vousden, 2005). The central core domain of the 393 amino acid protein binds to specific DNA sequences,

and its aminoterminal sequences have a transcriptional activation function (Figure 17-7). The carboxy-terminal sequences appear to be critical to the ability of the p53 protein to form homodimers and tetramers with itself. The p53 protein has been implicated in the positive regulation of several genes with critical roles in the control of the cell cycle, including the *p21WAF1/CIP1* gene, which regulates CDK activity, and the *GADD45* (for growth arrest DNA damage inducible) gene (Figure 17-8). Hundreds of other p53-induced genes have now been identified, including those encoding 14–3–3 sigma, which, like p53-induced *GADD45*, is reported to lead to cell cycle arrest in G2 and proapoptotic proteins such as PUMA and NOXA that now appear to represent critical p53 targets in triggering apoptosis (Hemann et al., 2004), and BAX. The transcription of *MDM2* is also positively regulated by p53, while that of ARF is reported to be repressed by p53, providing negative feedback control. This explains the detectable increase in p53 protein levels in tissues possessing mutated *TP53* that is transcriptionally inactive. The vast majority of the mutations identified in *TP53* alleles of human tumors inactivate the DNA-binding activity of the p53 protein and its ability to induce target gene expression. Based on its 3-D structure, many of the mutations affect amino acids that mediate p53's contact with DNA. In other cases, the mutations generate misfolded p53 proteins that can no longer bind to the specific DNA recognition sequence (Figure 17-6).

Other studies suggest that p53 may also function as a repressor of transcription and that this may contribute to the biological effects of p53. For example, p53 has been reported to repress expression of (a) the growth-promoting genes *C-FOS*, *C-MYC*, *IL2*, *IL4*, *IL6* and the insulin receptor; (b) the genes encoding the transcription factors, TBP, SP1, estrogen receptor, and hypoxia-inducible factor; and (c) the genes encoding the anti-apoptotic proteins, BCL-2, MAP4 and survivin (Slee et al., 2004). This repressive effect is believed to be mediated by the C-terminal region of p53 but, unlike p53's ability to activate transcription, it may not be sequence specific since many of the promoters of these

FIGURE 17-7

FIGURE 17-8

p53 transrepressed genes do not possess p53 binding sites (Slee et al., 2004).

Several cellular functions for p53 have been identified (Yee and Vousden, 2005). These include the regulation by p53 of the G1/S checkpoint of the cell cycle, preventing the cell from entering the DNA synthesis phase and also the ability of p53 to induce programmed cell death (apoptosis). Of great additional interest, particularly with regard to cancer pathogenesis and therapy, is that several studies have demonstrated that p53 possesses a critical role in the cellular response to DNA damage. Specifically, cells with wild-type p53 function appear to arrest in the G1 phase of the cell cycle in response to DNA damage thereby allowing the damaged DNA to be repaired before new DNA is synthesized. Cells lacking functional p53 fail to arrest and thus may replicate a damaged DNA template.

The ability of p53 to promote apoptosis appears to involve not only the transcriptional activation of proapoptotic activators such as PUMA and NOXA, but also an extra-nuclear p53 function. It is now recognized that p53 functions like the “BH3-only” proteins at mitochondria. It thus activates, by protein–protein interactions, the proapoptotic proteins BAX and BAK, leading to mitochondrial membrane permeabilization (Chipuk et al., 2004; Leu et al., 2004). The role of p53 in inducing apoptosis is crucial in preventing carcinogenesis. Mouse studies have indicated that the ability of p53 to induce a proliferative block, contributing to the maintenance of genomic stability, may be as important as the induction of apoptosis (Liu et al., 2004a, 2004b).

One of the goals of a number of ongoing drug-discovery programs is to identify small-molecule chemotherapeutic

agents that might restore or enhance wild-type p53 function in cancer cells. These agents might then be used either by themselves or in combination with conventional cytotoxic agents or radiotherapy. An apparently very promising approach is to inhibit the normal MDM–p53 interaction for instance by using small molecules to either inhibit the E3 ubiquitin ligase of MDM2 (Yang et al., 2005) or to block specific MDM2 interaction sites on p53 (Vassilev et al., 2004). Other future opportunities have arisen through the recognition of molecules other than ubiquitin that can modify and thus regulate p53, such as SUMO and NEDD8 (Hock and Vousden, 2010).

Somewhat surprisingly, there is growing evidence that the p53 protein possesses important roles that are distinct from the elimination (by inducing apoptosis or replicative senescence) of cells that have already acquired tumorigenic changes. In fact, it is now clear that p53 can act earlier, preventing oncogenic transformation of cells. It can achieve this by two principal mechanisms (Vousden, 2010). The first is by hindering the cancer-associated metabolic switch from oxidative phosphorylation to glycolysis, by either reducing the expression of genes necessary for glycolysis such as *GLUT1*, *GLUT4* and *PGM*, or by activating genes that drive mitochondrial respiration, such as *SCO2*. The second mechanism involves limiting oxidative damage by increasing the expression of particular genes, such as those encoding the antioxidant sestrin proteins—*SOD2*, *GPX1* and *ALDH4*—resulting in less reactive oxygen species (ROS)-induced DNA damage. Recent studies describing the p53-mediated activation of *GLS2* provide another example of the second mechanism, since *GLS2*, in turn,

leads to an increased availability of glutathione, which is an important intracellular scavenger of ROS (Hu et al., 2010; Suzuki et al., 2010). Moreover, it appears that the role of p53 in promoting antioxidant activities occurs under normal growth conditions, even without acute stress to the cell.

**17.5.3.4 Homologs and Isoforms of p53.** Two homologs of p53 have been identified: p73 and p63 (also known as Ket, p40, p51 and p73L). At least when overexpressed, both proteins mimic the ability of p53 to bind DNA and to induce gene transcription and apoptosis and several studies have detected p63 overexpression in many human cancers (Pruneri et al., 2005). Both *TP73* and *TP63*, the two corresponding genes, are rarely mutated in human cancer, with mutations occurring in <1% of tumors (Dotsch et al., 2010). Moreover, unlike p53-deficient mice, mice lacking p73 or p63 are not generally prone to tumors. Mutations in *TP63*, which is located at chromosome 3q27, have, however, been identified in several autosomal dominant human developmental syndromes. In general, these syndromes involve abnormal limb development and/or ectodermal dysplasia. They include ectrodactyly, ectodermal dysplasia, and clefting (EEC) syndrome; ankyloblepharon, ectodermal dysplasia, clefting (AEC or Hay–Wells) syndrome; acrodermato–ungual–lacrima–tooth (ADULT) syndrome; limb–mammary syndrome (LMS); and nonsyndromic split hand/foot malformation (SHFM). Interestingly, mutations associated with EEC and AEC syndromes tend to cluster within the DNA-binding domain and sterile-alpha-motif (SAM) domains, respectively. The SAM domain, which is located at the C-terminus, mediates protein–protein interactions. Many p63-regulated genes have now been identified in keratinocytes, including *IKKα*, *BPAG1* and *p21*; these genes have roles in differentiation, cell adhesion and proliferation, respectively (Pozzi et al., 2009).

Evidence has emerged that *TP73* may, too, play a role in normal development, with defects in neuronal development being reported in *p73* knockout animals (Dotsch et al., 2010). Interestingly, p73 induces apoptosis by not only transactivating *BAX* and *PUMA* but also through inducing ER stress by altering scotin expression and subcellular localization (Rossi et al., 2004).

Like *TP63* and *TP73*, which each have dual promoters, *TP53* has been shown, by David Lane's group, to possess an internal promoter, which is located within intron 4 (Bourdon et al., 2005). This results in an amino-terminal truncated p53 isoform, which is detected in most tissues. In addition, alternative splicing results in the absence of the exon 10-encoded amino acids in p53 beta and gamma. These isoforms consequently lack the oligomerization domain, cannot bind to certain normally p53-responsive promoters, and differ in proapoptotic activity. The beta isoforms have reduced proapoptotic activity and the beta isoform of amino-terminal truncated p53, in particular, is not only apoptosis defective,

but has a dominant-negative effect on the activity of the full-length isoform. The pattern of p53 isoform expression is complex, tissue specific, and often abnormal in tumors, with, for instance, reduced p53 gamma and upregulation of the N-terminal truncated p53. Interestingly, tumors that retain wild-type p53 often express an abnormal balance of p53 isoforms.

## 17.5.4 The Adenomatous Polyposis Coli Tumor Suppressor Gene

Hereditary CRC syndromes have long been recognized. The syndromes are usually divided into polyposis and nonpolyposis types. The polyposis types are those in which hundreds and sometimes even a thousand or more benign tumors (polyps) arise before the development of cancer. In the nonpolyposis types, very few polyps are noted, despite the very elevated risk of cancer. The nonpolyposis CRC syndromes are addressed later in this chapter. The well-documented polyposis syndrome, familial adenomatous polyposis (FAP), is an autosomal dominant disorder characterized by the development of hundreds of adenomatous polyps in the colon and rectum of the affected individuals by early adulthood together with congenital hypertrophy of the retinal pigment epithelium (CHRPE). The term Gardner syndrome has previously been used to refer to the occurrence of benign extracolonic tumors (including desmoid tumors, osteomas and dental abnormalities) in addition to the manifestations of FAP. But Gardner syndrome and FAP are now regarded as representing a disease continuum, caused by mutations in the same gene (and even by the same mutation within a single family) (Strate and Syngal, 2005).

The initial observation that led to the localization of the gene underlying adenomatous polyposis coli, *APC*, was the demonstration by Herrera and Sandberg and coworkers in 1986 of an interstitial deletion on chromosome 5q in a patient with hundreds of adenomatous polyps. Subsequent linkage analysis studies confirmed that in multiple kindreds with FAP or the related Gardner syndrome, the polyposis phenotype segregated with markers near 5q21. An intense research effort over the next 4 years identified the specific gene responsible for predisposition to polyposis: the *APC* gene. *APC* is a relatively large gene with the main transcript containing 15 exons and encoding a very large protein of 2843 amino acid residues (~300 kDa) that is expressed in many adult tissues. The predicted protein product shows little similarity to other proteins and is localized in the cytoplasm. It binds to beta-catenin, an abundant protein, much of which is normally bound to the cell–cell adhesion protein, E-cadherin. The beta-catenin–*APC* interaction occurs via two motifs on *APC*: One consists of three 15-amino acid repeats located between residues 1020 and 1169, while the other consists of seven 20-amino acid repeats located between residues 1324 and 2075, which can be

phosphorylated by the serine kinase, glycogen synthase kinase 3 (GSK3).

**17.5.4.1 APC Function and WNT Signaling.** In normal cells, as a member of a cytoplasmic complex that also contains constitutively active GSK3 and the scaffolding protein, AXIN, APC promotes the phosphorylation and subsequent proteosomal degradation of beta-catenin. However, if this phosphorylation of beta-catenin by GSK3 is inhibited, free beta-catenin accumulates (Figure 17-9). Such inhibition can occur either as a result of Wingless (WNT) signaling via the Frizzled receptor and the Dishevelled (DSH) protein, or through the loss of functional APC, as occurs in more than 80% of sporadic CRCs. Some of this excess beta-catenin moves into the nucleus where it forms a complex with T-cell factor 4 (TCF4), which then induces the transcription of growth and apoptosis regulating genes, including those encoding c-MYC, cyclin D, ephrins and caspases. The APC gene has thus been proposed to act as a “gatekeeper,” a gene which normally functions to maintain correct cell numbers by directly inhibiting abnormal cell proliferation or by promoting cell death. Mutations in *AXIN* and in *CTNNB* (encoding beta-catenin) have been detected in some hepatocellular carcinomas and in APC-wild-type colon tumors, respectively.

The beta-catenin/TCF4 complex also induces the expression of the nuclear hormone receptor named peroxisome-proliferator-activated receptor delta (PPAR-delta). This protein, following its activation by a ligand, can then induce the expression of other, unidentified, genes. Interestingly, nonsteroidal anti-inflammatory drugs (NSAIDs), which can, to an extent, reduce the size and number of polyps in FAP (Strate and Syngal, 2005),

appear to reduce the binding of PPAR-delta to DNA. This may occur by a cyclooxygenase-2 (COX-2)-independent mechanism, or by the inhibition of the COX-2-mediated production of PPAR-delta ligands such as eicosanoids, or by a combination of COX-2-dependent and -independent mechanisms. Importantly, this inhibition of PPAR-delta function appears to promote apoptosis of colon cancer cells.

Although the best-characterized function of APC is its role in regulating beta-catenin levels in the WNT signaling pathway, evidence is accumulating that interactions of APC with cytoskeletal proteins are also important to cancer development. For instance, lack of APC leads to chromosome missegregation and to mitotic spindle defects that can be rescued only by the addition of APC containing the direct microtubule-binding site (Dikovskaya et al., 2004). In addition, APC is now known to shuttle between the cytoplasm and the nucleus and the N-terminal region of the protein contains two nuclear export signals (NES). In early mitosis, APC is found to be localized to spindle microtubules, centrosomes and the ends of microtubules that are embedded in kinetochores (Nathke, 2004).

**17.5.4.2 APC Gene Mutations.** Mutations in the *MutYH* gene (see later section) should be considered in polyposis patients without family history evidence of vertical transmission, especially in those with an attenuated phenotype (i.e. less than 100 polyps) or a negative APC mutation screen. In most individuals affected by FAP or Gardner syndrome, however, germline mutations can be identified in one of the two APC alleles. The germline mutations in APC studied thus far generally appear to inactivate the protein. The mutations

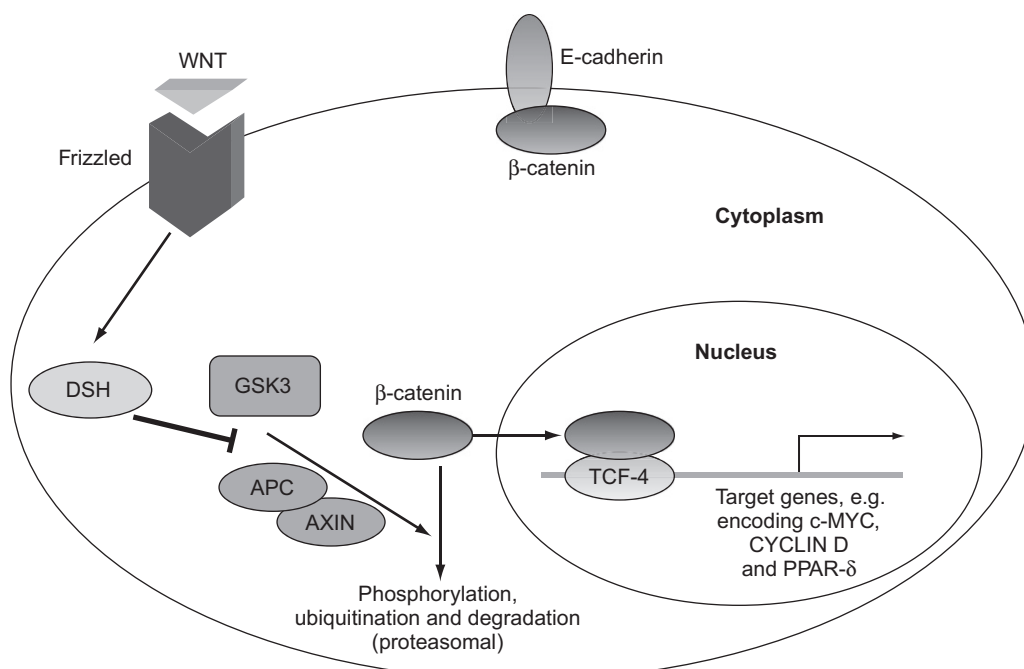

FIGURE 17-9

include gross deletions of the gene in a minority of cases, but, in the majority of cases, cause truncation by creating frameshifts or premature stop codons and result in the expression of N-terminal fragments of the protein (Nathke, 2004). An *APC* gene mutation database is currently available online at <http://www.insight-group.org/mutations/>. The second hit, present in most colorectal adenomas in FAP patients, is generally another truncating mutation, though, more rarely, is allele loss or LOH. Interestingly, in both sporadic and FAP colorectal tumors, the nature of the second *APC* gene hit appears to be dependent on that of the first. Thus, LOH tends to occur as the second hit when the first hit is a mutation lying close to codon 1300, or between codons 1285 and 1378. In contrast, truncating second hit mutations are preferentially selected when the first mutation lies outside the MCR. This association may reflect an “optimal” level of beta-catenin signaling for the development of colorectal tumors.

A genotype–phenotype correlation has emerged regarding the location of germline mutations within the *APC* gene. The amino terminal region of *APC* contains the putative oligomerization domains, two nuclear export signals and the armadillo repeats, which are reported to bind to various proteins, including the regulatory subunit of protein phosphatase 2A (PP2A) and the *APC*-stimulated guanine nucleotide exchange factor (ASEF) for Rho family proteins. The middle section of *APC* contains the binding sites for beta-catenin and axin. The less well conserved C-terminus contains the basic stretch that binds microtubules and is similar to the microtubule-binding site of TAU. Finally, the C-terminal 15 residues represent a PDZ-binding site.

Classical polyposis is generally associated with mutations located between codons 169 and 1403 with the occurrence of CHRPE being associated with mutations situated between codons 463 and 1387. Particularly profuse polyposis in *APC* may occur with germline mutations lying between codons 1285 and 1465, including the most common germline *APC* mutation, at codon 1309. In contrast, mutations located proximal to codon 157 of *APC* appear to correlate with an attenuated phenotype in which there are fewer polyps and a later age of onset of CRC. An explanation of the attenuated phenotype may be that these proximal mutations lead to the reinitiation of translation using an internal ribosome entry site and an in-frame ATG at codon 184 with the consequent production of an N-terminal truncated protein.

A predisposition to extracolonic tumors, which is especially evident in those said to have “Gardner syndrome,” appears to be associated typically with mutations located between codons 1403 and 1578 of *APC* (de la Chapelle, 2004). The studies reviewed above have provided definite support for the proposal that the loss of function mutations in the *APC* gene lead to predisposition to adenomatous polyps of the colon and

rectum. In addition, a valuable mouse model of intestinal tumorigenesis resulting from the inactivation of one allele of the murine homolog of the *APC* gene has also been described. This model is known as the Min (for multiple intestinal neoplasia) mouse. However, while FAP patients develop adenomatous polyps mostly of the colon and rectum, the Min mouse develops adenomatous polyps predominantly in the small intestine.

Currently, screening protocols for *APC* mutations generally involve DNA sequencing of the full gene to detect point mutations and small insertions or deletions, plus the use of multiplex ligation dependent probe amplification (MLPA) in order to detect larger duplications or deletions (i.e. leading to gene dosage alterations) (Necker et al., 2011). Two unrelated patients with classical polyposis coli (who did not have a significant family history and in whom no *APC* gene abnormality had been detected by these methods) were found by the protein truncation test (PTT) to possess a low level (15% or less) of mosaic pathogenic mutation, leading the authors to suggest that PTT should be retained as a diagnostic test (Necker et al., 2011).

Transcriptional silencing of the *APC* gene can occur by promoter inactivation such as by deletion. In this respect, it is important to note that the gene is governed by two promoters: 1A and 1B (Rohlin et al., 2011). The transcriptional activity of 1B has recently been reported to be higher than that of 1A and promoter 1B deletions can result in familial polyposis (Rohlin et al., 2011).

While germline inactivation of the *APC* gene is an infrequent predisposing factor of CRC, somatic inactivation of the *APC* gene appears to be critical in the development of the majority of sporadic colorectal adenomas and carcinomas. The chromosome 5q region containing the *APC* gene is affected by LOH in the majority of colorectal adenomas and carcinomas from patients without polyposis. Since the identification of the *APC* gene in 1991, detailed analyses of somatic *APC* mutations have been carried out (Figure 17-10). The somatic mutations identified in sporadic tumors have a similar spectrum and distribution to the germline mutations observed in those with FAP or Gardner syndromes. Present findings suggest that more than 70% of colorectal tumors and adenomatous polyps, regardless of their size or histopathological features, harbor a specific somatic mutation in one or both of their *APC* alleles. Gastric cancers are among the other tumor types that have been found to harbor mutations in the *APC* gene. In addition, *APC* gene inactivation may also be involved in the genesis of other tumor types. For example, patients with Turcot syndrome (in most cases, an allelic variant of FAP) are predisposed to the development of intestinal polyps and, also, primary brain tumors. Finally, a low-penetrance mutation in the *APC* gene, I1307K, has been identified, that is found almost exclusively in Ashkenazi Jews (see Section “Predisposition to Colorectal Cancer by Low Penetrance Genes”).

### 17.5.5 The Neurofibromatosis Type 1 Tumor Suppressor Gene

Type 1 neurofibromatosis (NF1) or von Recklinghausen disease has an incidence of ~1 in 4000 live births (Castle et al., 2003). It is a dominantly inherited syndrome whose principal manifestations involve tissues derived from the neural crest. In addition to neurofibromas and café-au-lait spots, NF1 patients are at increased risk of developing pheochromocytomas, optic gliomas, neurofibrosarcomas, and primary brain tumors. The *NF1* gene was localized to the pericentromeric region of chromosome 17q by linkage analyses carried out on several large kindreds with NF1. Subsequently, karyotype analysis led to the identification of two patients with NF1 and constitutional chromosomal translocations involving

band 17q11.2. Intensive molecular genetic analyses then focused on this region, and in 1990, the *NF1* gene was identified. Although recognized as the predominant underlying gene, *NF1* is not the only gene that causes this type of disorder as *SPRED1* is now known to cause an NF1-like disorder with multiple café-au-lait macules and axillary freckling but microcephaly rather than macrocephaly (Brems et al., 2007).

*NF1* is a large gene comprising 60 exons, spanning over 350 kb, and encoding a very large protein product with an estimated mass of 327 kDa. Around a half of affected individuals possess a de novo *NF1* mutation. The estimated new mutation rate of 1 in 10,000 is, in fact, one of the highest for a human disorder and most mutations are paternal in origin, although there is no

significant paternal age effect. Comprehensive mutation analysis of the gene is currently laborious on account of the gene's size and the large number of exons, the presence of several *NF1* pseudogenes and the wide spectrum of genetic lesions, including gross rearrangements and distinct point mutations. Many mutations have been described, of which around 80% are predicted to disrupt the encoded protein. For example, one mutation analysis study identified mutations in 64 (95%) of 67 unrelated *NF1* patients, of whom 37 had nonsense or frameshift mutations and 19 possessed splice-site mutations.

There are a few known genotype–phenotype correlations at present. In particular, a 1.4Mb recurring genomic deletion, encompassing 14 protein-encoding genes (including *NF1* gene) is associated with dysmorphic features, increased numbers of early-onset neurofibromas, and significant developmental delay (in addition to the typical *NF1* manifestations) (Castle et al., 2003). In addition, patients with deletions may be more predisposed to malignant peripheral nerve sheath tumors (MPNSTs) (De Raedt et al., 2003). In contrast, an exon 17 single codon deletion causes an unusually mild *NF1* phenotype without cutaneous neurofibromas (Upadhyaya et al., 2007). Furthermore, *NF1* patients who present with bilateral spinal neurofibromas have more missense and splice-site mutations than patients with classical *NF1* (Upadhyaya et al., 2009). It is likely that a number of modifier genes contribute to the phenotypic expression of the condition. Large investigations of over 1000 patients with *NF1* are currently underway to identify these genes by, for instance, genome-wide association studies (Huson et al., 2011).

In addition to germline *NF1* gene mutations in those with neurofibromatosis, somatic mutations inactivating the *NF1* gene have been found in a subset of other solid tumor types, including CRC, melanoma, neuroblastoma, and in some bone marrow specimens from those with the myelodysplastic syndrome. In benign neurofibromas, in accordance with the Knudson model of TSG function, the normal copy of the *NF1* gene often undergoes LOH or point mutation. The same is also true in *NF1*-associated MPNSTs, pheochromocytomas and astrocytomas (Frahm et al., 2004; Upadhyaya et al., 2004). Moreover, in benign neurofibromas, the Schwann cells, but not the fibroblasts, generally exhibit the loss of *NF1* transcript and neurofibromin, indicating that the abnormal cell in neurofibromas is the Schwann cell.

The 2818 amino acid protein encoded by the *NF1* gene is termed neurofibromin. It is localized in the cytoplasm of the cell and bears considerable similarity to the catalytic domains of GTPase-activating proteins (GAPs). One of the best studied GAPs is RAS-GAP, which has been shown to stimulate the (regulatory) GTPase activity of wild-type K-RAS, H-RAS, and N-RAS proteins. In addition to the predicted similarity of the neurofibromin protein to GAPs, studies have shown that neurofibromin

can, indeed, stimulate the GTPase activity of both yeast and mammalian RAS proteins (Arun and Gutmann, 2004). This activity of neurofibromin is envisaged, in vivo, to help prevent the overactivity of the RAS signaling proteins in the pathway which promotes cell proliferation. Thus, the loss of neurofibromin results in the abnormal persistence of the GTP-bound (i.e. active) form of RAS (Arun and Gutmann, 2004). The mechanisms by which *NF1* mutations alter cell growth are still not completely understood, however. They probably also involve interactions of neurofibromin with components of the cytoskeleton such as microtubules and intermediate filaments and a role of neurofibromin in positively regulating intracellular cAMP levels. Like *NF1*, *SPRED1* encodes a protein that negatively regulates signaling through the mitogen-activated protein kinase (MAPK) pathway. It does so by inhibiting RAS–RAF interaction (Brems et al., 2007).

The pathogenesis of MPNSTs in *NF1* patients is not yet well understood. It is known, however, to involve the deregulation of several key regulatory genes, such as *TP53*, *RB1*, *CDKN2A*, *EGFR*, *PDGFR*, *PDGFRA*, *HGF*, *MET* and *SOX9* and the constitutive activation of multiple cell signaling pathways (Upadhyaya, 2011).

### 17.5.6 The *CDKN2A* Gene

Loss of heterozygosity affecting chromosome 9p has been seen frequently in a wide spectrum of tumors, including melanomas, gliomas and leukemias as well as bladder, head and neck and non-small cell lung cancers. A subset of tumors was found to have homozygous deletions affecting the 9p21 region. In addition to the frequent somatic alterations on 9p in cancers, linkage studies of some families with inherited melanoma established that a melanoma predisposition gene mapped to 9p.

These findings motivated efforts to define a more limited region of chromosome 9p that was presumed to contain a TSG affected by both germline and somatic mutations. One of the genes identified in this region of 9p as a result of positional cloning efforts was termed *MTS1* (multiple tumor suppressor 1). Sequence analysis of the *MTS1* gene revealed that it was identical to a previously identified gene *p16*. The *p16* (now named *CDKN2A*) gene was originally identified because it encoded a protein (now termed p16INK4A) that functions as a specific inhibitor of cyclin-dependent kinases CDK4 and CDK6. The *CDKN2A* gene encodes not only the p16INK4A but also, as the result of an alternative reading frame, the p14<sup>ARF</sup> protein. The *CDKN2A* gene has been found to be mutated in the germline DNA of around 25–40% of individuals with familial cutaneous malignant melanoma (CMM). Mutations in this gene result in a lifetime risk of CMM of between 50 and 80% depending on the level of ambient sun exposure (Bishop et al., 2002). As in other disease-related genes, certain mutations are far more commonly found than others,

depending on the population. The M53I mutation, for instance, is a recurrent mutation that is pathogenic and, from haplotype analyses, appears to have a Scottish origin (Lang et al., 2007).

In familial CMM, there have been, in addition, at least two reports of germline *CDKN2A* exon 1 beta (which encodes p14<sup>ARF</sup>), and even *CDKN2A* intronic mutations (Harland et al., 2005a, 2005b). Somatic mutations in *CDKN2A* have, in fact, been found in a significant fraction of many different cancer types, including but not limited to melanomas, gliomas, pancreatic and bladder cancers, and leukemias. In some of these tumors, deletions of the *CDKN2A* gene were also found to involve a nearby gene, *p15*, that encodes a protein closely related to *CDKN2A*. In other tumors, mutations have been found that appear to inactivate *p15*, but not *CDKN2A*.

The *CDKN2A* gene, as mentioned above, has been shown to encode a second unique protein (in addition to the p16 protein). This protein is termed p14<sup>ARF</sup> in humans and p19<sup>ARF</sup> in mouse. Both the p16INK4A and the p14<sup>ARF</sup> proteins have been found to possess growth suppressive functions. Hence, there may be strong selection for simultaneous inactivation of both proteins during tumor development.

The prevalence and nature of *CDKN2A* mutations appear to vary markedly from one tumor type to another, and the gene appears to be more frequently mutated in tumor cell lines adapted for culture than in primary tumors. This finding may reflect the fact that *CDKN2A* inactivation may provide an additional growth advantage to cultured tumor cells. Homozygous deletion is a particularly common mechanism by which *CDKN2A* has been found to be inactivated in some primary human tumors and tumor cell lines. Other studies suggest that p16INK4A expression is lost in some tumor types as a result of methylation of the gene's regulatory sequences (i.e. promoter/enhancer elements), a situation that in several other genes often results in the loss of gene expression. In fact, the finding of *CDKN2A* inactivation by DNA methylation led to the investigation and subsequent widespread acceptance of DNA methylation as a general mechanism for the inactivation of TSG function during tumorigenesis. As discussed above for the *RB1* and *TP53* genes, the frequent inactivation of the *CDKN2A* gene in a wide spectrum of human cancers underscores the importance of the physiological control of the cell cycle in normal cell growth and in the suppression of the neoplastic phenotype.

Mutations in another cell cycle control gene, *CDK4*, are much less frequently found in familial CMM although there is a specific mutational hot spot at codon 24. As mentioned previously, *CDK4* is one of the few examples of a familial cancer gene that is a proto-oncogene rather than a TSG. It is unlikely, however, that *CDKN2A* and *CDK4* are the only genes that cause familial CMM. A locus that is believed to harbor another pathogenic gene

is 1p36. At this locus, a possible CMM TSG is *CHD5* (Lang et al., 2011) although further studies are required before this can be confirmed. Other melanoma susceptibility genes are likely to be identified in the future.

### 17.5.7 P16INK4a and P14<sup>ARF</sup>/P19<sup>ARF</sup> Functions

The p16INK4A protein is a CDK inhibitor that maintains pRB in its growth-suppressive, hypophosphorylated state. In contrast to p21<sup>WAF1</sup>, whose expression in replicating fibroblasts increases sharply just before the onset of replicative senescence but then declines, p16INK4A expression increases gradually to a sustained, greatly elevated level in the later stages of senescence. Thus, while p21<sup>WAF1</sup> may be responsible for the induction of senescence, p16INK4A may be essential for its maintenance. While inactivation of the p19/p53 pathway is sufficient for murine cells to escape senescence, human cells generally need to disrupt, at least, both the p53/p21 and the p16INK4A/pRB pathways (Figure 17-8). Perhaps as a consequence, human cells spontaneously immortalize in culture much more rarely than rodent cells.

### 17.5.8 *WT1*, the Wilms' Tumor Suppressor Gene at Chromosome 11P13

Similar to retinoblastoma, and despite its relative rarity compared to common adult tumors, Wilms' tumor has provided a number of critical insights into TSG identification and function. The first findings to suggest the contribution of a gene at 11p13 to the development of Wilms' tumor were those of Miller and coworkers in 1964. They noted an association between aniridia (a congenital absence of the iris) and Wilms' tumor. Further studies confirmed that a rare complex of developmental abnormalities, including aniridia, genitourinary malformations, and mental retardation, was associated with a high probability of developing Wilms' tumor, hence the acronym WAGR (Wilms' tumor with aniridia, genitourinary malformations, and retardation) syndrome. Similar to the situation observed in some patients with inherited retinoblastoma and deletion of chromosome 13q14 sequences, some patients with WAGR syndrome were found to have constitutional deletions involving part of one copy of chromosome 11, at band p13. Based on these data, it was inferred that one of the genes involved in Wilms' tumorigenesis must reside at 11p13 and the *WT1* gene was identified in 1990. In fact, the hemizygous chromosomal deletion, often cytogenetically visible, in children with WAGR syndrome encompasses not only *WT1* but also generally at least the *PAX6* gene, and WAGR is therefore regarded as a "contiguous gene syndrome."

The *WT1* protein is a zinc-finger transcription factor of 55 kDa that is encoded by 10 exons. The mRNA produced is subject to a complex pattern of alternative splicing involving exons 5 and 9. The significance of exon 5

alternative splicing is currently unknown as mice lacking this exon develop normally and are fertile. In contrast, alternative splicing of exon 9 results in either WT1 “-KTS” or “+KTS” isoforms in which three amino acids (lysine, threonine and serine) are either absent or present, respectively, between zinc fingers three and four. This three-residue insertion results in different DNA-binding properties of WT1 and in altered kidney and gonad development in mice, and in humans affected by Frasier syndrome (Rivera and Haber, 2005). WT1 (+KTS) is the most abundant form and colocalizes with splicing factors and small nuclear ribonucleoproteins (snRNPs) within nuclear “speckles” (Rivera and Haber, 2005).

Based on the predicted amino acid sequence, the WT1 proteins appear to function in transcriptional regulation, and evidence has been obtained that the WT1 protein may suppress the expression of several growth-inducing genes, including the early growth response (*EGR1*), insulin-like growth factor II (*IGF2*), and platelet-derived growth factor A (*PDGFA*) genes. WT1 has also been shown to induce the expression of the pro-apoptotic factors, BAK and BIK, and may also repress the expression of the anti-apoptotic factor, BCL2 (Morrison et al., 2005). It appears likely therefore that inactivation of WT1 results in Wilms’ tumor development as a result of not only increased cellular proliferation but also failed apoptosis during kidney development.

Although Wilms’ tumor is a relatively common childhood tumor, true familial Wilms’ tumor is very rare (Rivera and Haber, 2005). Mutations in the *WT1* gene are present in just 10–15% of sporadic cases of Wilms’ tumor. It is now recognized that Wilms’ tumor can occasionally occur as part of a number of syndromes, including not only WAGR but also Denys-Drash, Frasier, Beckwith-Wiedemann, Simpson-Golabi-Behmel, Sotos, and Perlman and Familial Wilms’ Tumor 1 and 2 syndromes (Rivera and Haber, 2005). In patients with Denys-Drash syndrome (DDS), there is typically a germline missense mutation, causing a single amino acid substitution most often at Arg 394 of WT1, rather than the hemizygosity associated with WAGR syndrome (Royer-Pokora et al., 2004). In fact, in DDS, the phenotypic severity is greater than that of in WAGR syndrome, possibly reflecting a dominant negative effect of the mutant WT1.

### 17.5.9 The *NF2* Gene and Merlin

Neurofibromatosis type 2 (NF2), also known as central neurofibromatosis, is an autosomal dominant disorder that is genetically and clinically distinct from NF1 and is ~10 times less common. The hallmark of NF2 is the occurrence of bilateral schwannomas affecting the vestibular branch of the eighth cranial nerve (acoustic neuromas). In addition, NF2 patients are also at risk of the development of other tumors, including cranial and spinal meningiomas, spinal schwannomas, and ependymomas. The *NF2* gene was localized to chromosome 22q in the late 1980s

by a combination of linkage analyses and LOH studies. The gene was identified in 1993 using a positional cloning approach. It spans 110kb and comprises 16 constitutive and one alternatively spliced exon. The gene is widely expressed both in terms of tissues and individual cell types. Germline mutations inactivating the *NF2* gene have been observed in those with NF2, and patients with truncating mutations generally have an earlier onset and an increased number of tumors. In addition, large deletions have been reported to account for as many as 33% of *NF2* gene alterations. Somatic mutations in the gene have been detected in up to 60% of sporadic schwannomas and also in 70% and 83% of sporadic fibroblastic and transitional meningiomas, respectively. Mutations of the *NF2* gene have also been detected in up to 30% of melanomas and 41% of malignant mesotheliomas.

The *NF2* gene encodes a protein of 595 amino acids named merlin that bears strong similarity to a family of cytoskeletal proteins that are thought to act as linker proteins that connect integral membrane proteins to cytoskeletal scaffolding proteins of the filamentous submembrane lattice. These “ERM” linker proteins, ezrin, radixin and moesin, each possess an N-terminal FERM domain, a long alpha-helical central region, and a charged C-terminal domain that binds to F-actin and can interact intramolecularly with the N-terminal region. The intramolecular interaction but not the F-actin binding is a property of schwannomin and appears to be necessary for the protein’s tumor suppressor function. The presence of the alpha-helical central region may permit merlin to form a stable interaction, as a coiled-coil, with another ERM protein or with other proteins such as the coiled-coil protein, SCHIP-1. The homology of merlin and ERM proteins suggests a number of possible mechanisms by which *NF2* gene alterations might affect the cell shape, cell-cell interactions, and tumor growth. Several proteins have been reported to interact with merlin but such studies have been hampered by technical difficulties relating, for instance, to merlin solubility. The tumor suppressor activity of merlin relates to its role in both the coordination of growth factor receptor signaling and cell adhesion (McClatchey and Giovannini, 2005). For instance, merlin binds to GRB2, an adaptor protein that coordinates receptor tyrosine kinase and RAS signaling (Wiederhold et al., 2004) and to Lin-7/Pals1, which, in *Caenorhabditis elegans*, controls Erb-B2 membrane distribution (Cao et al., 2005). In addition, several studies suggest that merlin is essential for contact-dependent inhibition of proliferation.

Merlin is phosphorylated on several sites but the best studied is serine 518. Phosphorylation on S518 inactivates merlin’s growth suppressing activity and inhibits its self-association. Kinases that promote this phosphorylation include the major RAC effector p21-activated kinase (PAK) and also protein kinase A (PKA) (Alfthan et al., 2004). Therefore, the activity of merlin is likely to be intracellularly regulated by several routes. Merlin is,

in fact, now believed to play an important tumor-suppressive role within the nucleus (such as the regulation of mitogenic signaling via inhibition of the MAPK cascade or via an effect on the hippo protein), as well as at the cell surface (Huson et al., 2011; Yi and Kissil, 2010). Its relative contributions at each location, however, remain to be determined (Huson et al., 2011).

### 17.5.10 The *VHL*, *SDH* and *TMEM127* Genes

VHL syndrome is a rare, dominantly inherited disorder that predisposes individuals to the development of hemangioblastomas of the central nervous system and retina, as well as renal cell carcinomas and pheochromocytomas. The *VHL* gene was assigned to chromosome 3p by linkage analysis, and LOH studies were used to establish that the gene behaves as a typical tumor suppressor, as defined by Knudson's model, wherein both the alleles are inactivated during tumorigenesis. A positional cloning approach was successfully employed to identify the *VHL* gene and germline inactivating mutations that are responsible for VHL. Somatic mutations in the *VHL* gene have also been detected in most sporadic renal cell carcinomas of the clear cell type but not in other histological subtypes of renal cell carcinoma. Interestingly, in many of the sporadic clear cell renal cancers that do not harbor a detectable mutation in the *VHL* gene, the *VHL* gene is inactivated by methylation of its transcriptional regulatory sequences, as occurs with other TSGs such as the *CDKN2A*, *MLH1*, *CDH1* and *BRCA1* genes. Therefore, the *VHL* gene plays a critical role in the pathogenesis of the most common form of adult renal cancer. In other tumor types, however, inactivation of the *VHL* gene by somatic mutations or methylation appears to be uncommon.

Initial studies demonstrated that the *VHL* gene encodes a 213 amino-acid residue protein, pVHL, that complexes with the B and C subunits of the elongin transcriptional elongation factor, forming a protein complex that appeared to regulate transcriptional elongation by RNA polymerase II; however, no regulation of transcriptional elongation by pVHL has been shown in vivo. Rather, pVHL appears to participate in a regulatory mechanism that normally prevents inappropriate accumulation of a transcription factor—hypoxia-inducible factor (HIF) 1 alpha—that stimulates the transcription of hypoxia-responsive genes such as vascular endothelial growth factor (*VEGF*) and *EPO* (Kim and Kaelin, 2004). The VHL protein comprises two domains. Its alpha domain functions as a platform on which a complex is assembled, including elongin C, elongin B, Cul2 and Rbx1 (known, collectively, as the VCB–Cul2 complex). The pVHL beta domain has been shown to bind to the oxygen-dependent degradation domain of the alpha subunit of HIF1. By structural comparisons of the VCB–Cul2 complex with the yeast SCF complex, and

by extensive studies of pVHL activity, it is now recognized that (1) HIF1-alpha, under normoxic conditions, undergoes ubiquitin-mediated degradation; (2) the ubiquitination of HIF1-alpha is dependent on its interaction with the ubiquitination machinery of the VCB–Cul2 (or VCBC) complex (which functions as an E3 ubiquitin ligase) via the beta domain of pVHL; (3) this ubiquitination is disabled either in hypoxic conditions or as a consequence of most *VHL* mutations; and (4) this disabling leads to HIF1-alpha accumulation and the activation of hypoxia-responsive genes such as *VEGF*, which is an important factor in tumor angiogenesis.

The oxygen sensitivity of the degradation of HIF1-alpha is due to the fact that the transcription factor undergoes hydroxylation only under normoxic conditions and the hydroxyl groups then form the binding site for pVHL (Kim and Kaelin, 2004). The hydroxylation takes place on evolutionarily conserved proline residues (Pro-402 and Pro-564) and is carried out by prolyl hydroxylase enzymes of the so-called EGLN (Egl-nine) family. In addition, X-ray crystallography has revealed that the prolyl hydroxyl groups can then form hydrogen bonds with two hydrophilic residues of pVHL.

The prolyl hydroxylases split molecular oxygen and not only hydroxylate the prolyl substrate but also form succinate. The latter—a TCA cycle intermediate—is converted to fumarate by succinate dehydrogenase (SDH). Inherited and somatic mutations in *SDH* genes (particularly *SDH-B* and *SDH-D*) have been shown to be associated with pheochromocytomas and paragangliomas. The *SDH-B* mutations tend to be associated with a more aggressive disease and a poorer prognosis. Intriguingly, tumorigenesis associated with germline *SDH-D* mutations, specifically, has been reported to result exclusively from paternal transmission of the mutations and this may be explained by imprinting of a chromosome 11 gene other than *SDHD* itself (Hensen et al., 2004). There is accumulating evidence, in fact, that this gene lies on the short arm of chromosome 11 and that tumor formation can, rarely, occur after maternal transmission. In addition, in view of the biochemistry of prolyl hydroxylases, it was hypothesized and then demonstrated in an elegant study, that a crucial link between *SDH* mutations and tumor formation might be that succinate, having accumulated as a result of reduced SDH activity, might inhibit prolyl hydroxylation of HIF1-alpha by product inhibition of the prolyl hydroxylase, leading to HIF1-alpha stabilization and activation (Selak et al., 2005). The EGLN prolyl hydroxylases have now become a focus of much research into pheochromocytomas and other tumors (Maxwell, 2005).

Recently, mutations in another gene, *TMEM127* (which encodes a negative regulator of mTOR), and (albeit rarely) in another chromosome 11 gene, *SDHAF2* (encoding a cofactor of the SDH complex), have been reported to be associated with familial

phaeochromocytomas and paragangliomas, respectively (Qin et al., 2010; Bayley et al., 2010).

### 17.5.11 E-cadherin

E-cadherin is a calcium-dependent, epithelial cell–cell adhesion molecule whose function is critical for normal epithelial development and is lost during the growth of most, if not all, human epithelial cancers. In particular, somatic loss of its expression is regarded as being a characteristic feature of both diffuse gastric cancer and lobular breast cancer (Brooks-Wilson et al., 2004). It is a transmembrane glycoprotein and binds to (and thus sequesters at the cell membrane) beta-catenin, a protein which, when released, can, together with the TCF4 transcription factor, activate growth-promoting genes such as c-MYC (Figure 17-9). Beta-catenin is also negatively regulated by the APC/AXIN/GSK3 complex (see Section “APC Function and WNT Signaling”). Inactivation of the alleles of the *CDH1* tumor suppressor gene (which encodes E-cadherin) may occur by deletion, point mutation, or promoter hypermethylation. Germline *CDH1* mutations were originally identified in three diffuse gastric cancer kindreds of Maori origin and are now a well recognized cause of familial gastric cancer (of diffuse but not intestinal type) and are generally detected in around a third of families with two or more cases of diffuse gastric cancer; that is, hereditary diffuse gastric cancer (HDGC). *CDH1* mutations were, however, detected in as many as 48% of such families when an additional selection criterion (of age at diagnosis of 50 or less) was used (Brooks-Wilson et al., 2004). The authors of that study concluded that mutation analysis is unlikely to yield a *CDH1* mutation unless the family history includes two or more individuals with gastric cancer of whom at least one represents a documented case of diffuse gastric cancer (DGC) diagnosed at the age of 50 or younger (Brooks-Wilson et al., 2004). The association of *CDH1* mutations with early onset diffuse gastric cancer has been confirmed by a more recent analysis (Corso et al., 2011). Carriers of pathogenic germline *CDH1* mutations are estimated to possess a cumulative risk by age 80 of gastric cancer of ~67% for men and 83% for women, who may also have a risk of breast cancer of almost 40% (Brooks-Wilson et al., 2004).

Inactivation of the wild-type allele in germline *CDH1* mutation carriers generally occurs by transcriptional silencing due to promoter methylation. Interestingly, *CDH1* promoter hypermethylation has been detected on both alleles of the gene in two patients with sporadic leukemia, as has been previously observed for *MLH1* in sporadic CRCs. In many sporadic human cancers, loss of E-cadherin expression occurs late in the process of tumorigenesis and is associated with metastasis. This fact, together with its role as a cell–cell specific recognition receptor, suggests that the protein functions as an “invasion suppressor.” Loss of E-cadherin is believed to

promote invasion through the loss of cell adhesion but also to promote mitogenesis via increased beta-catenin signaling (Hayashida et al., 2005). The cell-to-cell adhesion that is mediated by E-cadherin is inhibited by the overactivity of the oncogene product, Src tyrosine kinase (Swaminathan and Cartwright, 2011).

### 17.5.12 The *PTEN* Gene

An extensive linkage analysis involving a genome scan of 12 classical Cowden syndrome (CS) families localized the gene to 10q23. In addition, frequent LOH at this locus was found in follicular thyroid tumors, suggesting that the putative CS gene was a tumor suppressor. Subsequently, two independent groups isolated a novel gene at this locus. Sequence analysis predicted that the gene would encode a protein with homology to the cytoskeletal proteins, tensin and auxilin, and that the protein would contain a protein tyrosine and serine/threonine phosphatase domain. The new gene was named *PTEN*, for phosphatase and tensin homolog on chromosome 10.

An increasing number of disorders are being associated with *PTEN* (Pilarski and Eng, 2004). These disorders constitute a group named the *PTEN* hamartoma tumor syndromes (PHTS) (Eng, 2010). For instance, germline mutations in the *PTEN* gene are now being found in around 80% of individuals with CS, in 50–60% of those with another related dominantly inherited disorder, Bannayan–Zonana (or Bannayan–Riley–Ruvalcaba syndrome (BRRS)) syndrome, in 20% of those with Proteus syndrome, and 50% of those with a Proteus-like syndrome (Nagy et al., 2004). Germline mutations in *PTEN* are now also known to cause Lhermitte–Duclos disease, or dysplastic gangliocytoma of the cerebellum. It is not clear whether the CS cancer risks (e.g. for breast, follicular thyroid, and endometrial cancers) are applicable also to those non-CS patients who possess *PTEN* mutations, but it has been suggested that they should be screened like those with CS (Nagy et al., 2004). On the basis of a study of over 3000 probands, a new clinical scoring method for the selection of patients for *PTEN* analysis has been proposed by Charis Eng and colleagues (Tan et al., 2011).

In common with many other TSGs (although not *TP53*), the majority of mutations result in protein truncation. Although the mutations are scattered over the entire gene, clustering is observed in the phosphatase core motif in exon 5 and in the phosphorylation sites in exons 7 and 8. Specific germline *PTEN* mutations may give rise to either CS or BRRS, even within the same family, but there is a tendency for CS-associated mutations to be located within the 5′ five exons and for the BRRS-related mutations to be sited within the 3′ exons.

The tumor suppressor function of the *PTEN* protein, the first TSG to be identified in the phosphatase family, appears to depend on its lipid phosphatase, rather than its protein phosphatase, activity. In particular, its

critical activity is the dephosphorylation of the lipid second messengers phosphatidylinositol 3,4-bisphosphate and phosphatidylinositol 3,4,5-trisphosphate (PIP3), at position 3 on the inositol ring, thus antagonizing the phosphoinositide 3-kinase (PI3K)/Akt signaling pathway and resulting in either cell cycle arrest in G1 and/or apoptosis depending on the tissue type (Nagy et al., 2004). Cells derived from the embryos of homozygous PTEN knockout mice do show elevated levels of PIP3 and constitutively increased activity of the PKB/Akt enzyme, consistent with the role of PTEN in the inhibition of the PI3K pathway. Moreover, they exhibit a reduced sensitivity to apoptosis, consistent with a role of PTEN in the negative regulation of cell survival.

When PTEN is inactive, Akt (also known as protein kinase B or PKB) promotes cell cycle entry, cell survival and cell growth by phosphorylating several key substrates. These include NF-kappaB, forkhead transcription factors, GSK3, p27, caspase 9, BAD, MDM2 and TSC2. Phosphorylation of tuberous sclerosis complex 2 (TSC2) results in the degradation of the TSC1–TSC2 complex, resulting in the increased activity of mTOR and consequently that of the cell size regulator, S6K. In addition, evidence suggests that mTOR also mediates a feedback loop as it can, itself, phosphorylate and activate Akt (Guertin and Sabatini, 2005). Although a great deal has thus been revealed regarding the importance of the lipid phosphatase activity of PTEN, the precise role of the protein phosphatase activity of PTEN remains much less clear.

## 17.6 THE ROLE OF DNA DAMAGE REPAIR GENES IN INHERITED CANCER SYNDROMES

Tumor suppressor genes have been defined strictly in this chapter as the class of genes that are inactivated by germline and somatic mutations in cancers and that normally have active roles in the regulation of cell growth in response to growth-inhibitory or differentiation signals. Though they are also inactivated in cancer cells, the DNA damage repair genes can be viewed as having more indirect roles in the processes controlling growth. Loss-of-function mutations in these genes are presumed to have little direct effect on cell growth. Rather, their inactivation appears, in affected cells, to increase the rate of mutations in cellular genes, including proto-oncogenes and tumor suppressor genes. The DNA damage repair genes may, however, for simplification, be regarded as a subset of TSGs in view of the requirement for their mutational *inactivation* for tumorigenesis.

Several cancer predisposition syndromes have now been described that result from germline mutations inactivating genes involved in DNA damage repair. These include hereditary breast/ovarian cancer, xeroderma pigmentosum, Werner syndrome (WS), Bloom syndrome (BS), Nijmegen breakage syndrome (NBS), ataxia

telangiectasia, MutYH-associated polyposis (MAP) and the hereditary nonpolyposis colorectal cancer (HNPCC) syndromes. The principal mechanisms of DNA repair include (a) mismatch repair of mispaired bases (mainly from errors arising in DNA replication), (b) repair by homologous recombination (or by end joining) of double-strand breaks (DSBs) (induced, e.g. by X-rays), (c) nucleotide excision repair of intrastrand pyrimidine dimers, induced by UV light, and (d) base excision repair (BER) of small-base modifications caused, for example, by oxygen radicals and alkylating agents.

### 17.6.1 Hereditary Breast Cancer and the *BRCA1* and *BRCA2* Genes

It has long been known that family history is a major contributor to breast cancer risk and that the risk is greatest in those who have a history of breast cancer in one or more first-degree relatives. However, it was not until the late 1980s that definitive evidence was obtained that the predisposition to premenopausal breast cancer in some families could be attributed to a highly penetrant autosomal dominant allele. Subsequently, Hall, King, and their coworkers reported in 1990 that one such gene, now termed *BRCA1* (for breast cancer predisposition gene 1), mapped to chromosome 17q21. Other investigators subsequently provided evidence that the *BRCA1* locus was associated with susceptibility to both breast and ovarian cancers. On account of the intensive research efforts that were focused on the chromosome 17q region thought to contain the gene, *BRCA1* was ultimately identified in 1994.

While germline mutations in the *BRCA1* gene account for around 50% of the families in which four or more members are affected by breast cancer at an early age, ~30% of such kindreds have been attributed to mutations of another highly penetrant autosomal dominant susceptibility gene termed *BRCA2*. The *BRCA2* gene was mapped to chromosome 13q12–13 in 1994 and was subsequently identified. Mutations in *BRCA1* and *BRCA2* appear to confer, in the high-risk families studied, similar “lifetime” risks of female breast cancer, of up to around 80% (Narod and Offit, 2005). The risk of ovarian cancer appears considerably higher in those with *BRCA1* mutations than in those with *BRCA2* mutations, at 54% and 23%, respectively (King et al., 2003). Conversely, the risk of breast cancer in males with a *BRCA2* mutation (around 6%) is substantially higher than in males with a *BRCA1* mutation. The risks of other cancers are not yet clear, but may include prostate and colon cancers for *BRCA1*. For *BRCA2* mutation carriers, statistically significant increases in risk were observed, by the Breast Cancer Linkage Consortium, for malignant melanoma and for prostate, pancreatic, gall-bladder, bile duct and stomach cancers. Perhaps not surprisingly, in population-based studies, the penetrances of *BRCA1* and *BRCA2* mutations appear to be significantly lower than in high-risk families, probably on account of the presence or absence

of risk-modifying gene variants (see Section “*BRCA1* and *BRCA2* Mutations and Cancer Predisposition”).

**17.6.1.1 Structure and Function of the *BRCA1* Protein.** The *BRCA1* gene contains 24 exons, of which the first is noncoding, with exon 11 encompassing about half of the coding sequence. It encodes a 220 kDa nuclear protein, BRCA1-p220, of 1863 amino acid residues, which appears to interact with a variety of proteins that have diverse cellular functions (Figure 17-11).

At its amino terminus is a zinc-binding RING finger domain. Ring fingers are evolutionarily conserved structures consisting of two loops held together at their base by eight histidine or cysteine residues and two zinc ions. They can function, rather like the pVHL protein complex, as ubiquitin–protein ligases or E3s. In addition, the RING finger of BRCA1 can bind to the RING finger of another protein-designated, BRCA1-associated RING domain 1 (BARD1), thus forming a heterodimeric BRCA1–BARD1 complex. The BRCA1–BARD1 complex inhibits polyadenylation by binding to the polyadenylation factor CStF-50 and may thus prevent inappropriate RNA processing at the sites of DNA repair. The heterodimer may also ubiquitinate topoisomerase II alpha and may thus possibly play a role in chromatin decatenation (or disentangling), for instance of sister chromatids at the onset of anaphase (Ashworth, 2005).

Located in the central portion of BRCA1 are three putative nuclear localization signals (NLS). Two of these regions of highly charged basic residues were found to interact with a component of the NLS receptor complex, importin- $\alpha$ , in a yeast two-hybrid screen using BRCA1 as the bait. Located at the extreme C terminus are two BRCT (BRCA1 C-terminal) repeats. BRCT domains are evolutionarily conserved regions, of ~95 amino acids residues, whose 3-D structure suggests a role in protein–protein interactions and which are found in many proteins involved in DNA repair and cell cycle control. While almost all identified mutations in *BRCA1* result in a truncated product, yielding little functional information, many missense mutations have been found.

These are located predominantly within either the RING finger domain or the BRCT repeats, providing support for the functional importance of these regions.

The role of BRCA1 in tumor suppression may involve a combination of DNA repair, transcriptional regulation, cell-cycle control and possibly apoptosis. Evidence that it is involved in DNA repair includes the observation that (a) BRCA1-deficient embryonic stem (ES) cells are hypersensitive to both ionizing radiation and hydrogen peroxide, and also that (b) such cells have impaired transcription-coupled DNA repair and homology-directed chromosomal DSB repair. In addition, following DNA DSBs BRCA1 appears to be phosphorylated by ATM, ATR, or CHK2 (Turner et al., 2005). ATM phosphorylates BRCA1 at its SQ cluster domains (SCDs), which represent clusters of serine and threonine sequences (Narod and Foulkes, 2004). Moreover, the BRCT domains of BRCA1 have been reported to bind to the ends of linear DNA fragments, independent of the DNA sequence, although, as mentioned above, they may also participate in protein–protein interactions.

Previous studies have found that BRCA1 interacts, through the C-terminal end of the region encoded by exon 11, with both RAD51 and RAD50. RAD51 is the human homolog of the yeast RecA protein, which functions in homologous recombination and DNA damage repair. Significantly, RAD51 is known to form a complex with both BRCA1 and BRCA2 during DNA repair. Similarly, on induction of DNA damage, RAD50 forms a complex with BRCA1, MRE11 and NBS1/p95/NIBRIN (the protein encoded by the gene mutated in NBS). Through these interactions, BRCA1 is believed to assist in the maintenance of genomic integrity, principally by promoting the potentially error-free homologous-directed DNA DSB repair in preference to the error-prone, potentially mutagenic, mechanisms such as nonhomologous end joining (NHEJ) and single-strand annealing (SSA) (Turner et al., 2005).

With regard to transcriptional regulation by BRCA1, a region between amino acids 1142 and 1646 and a

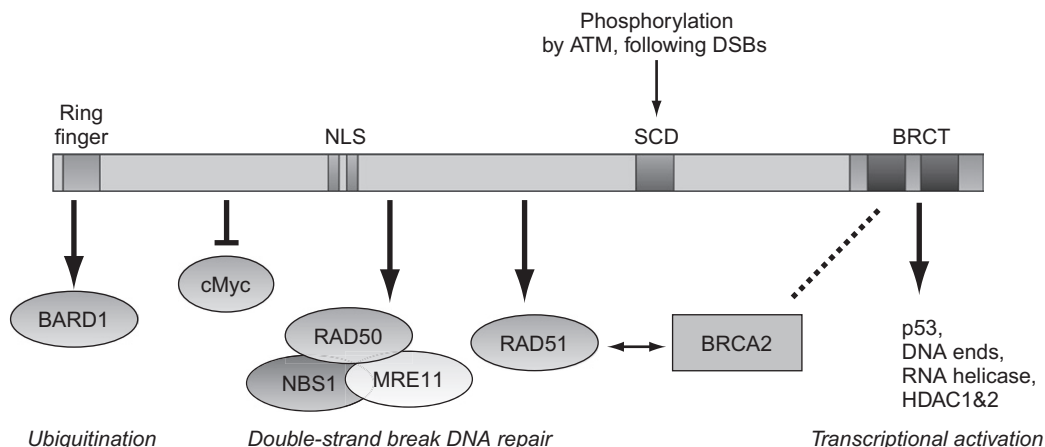

FIGURE 17-11

domain encompassing the carboxy-terminal residues 1760–1863 have been shown to possess transactivation activity. Additionally, evidence is accumulating that BRCA1 functions as a transcriptional regulator by interacting with other proteins, including sequence-specific binding proteins. For instance, BRCA1 interacts with both the transcriptional transactivator, c-MYC, whose activity it inhibits, and the RNA helicase A. Furthermore, the BRCT domain, located between amino acids 1536 and 1863 of BRCA1, can also bind to components of the histone deacetylase complex (HDAC). The implied function of BRCA1 in the regulation of chromatin remodeling could, theoretically, contribute to transcription, replication, recombination, or DNA repair. The BRCA1 C-terminal region also interacts with p53, appearing to stimulate its transcriptional activation of the *p21* gene, and with the RNA polymerase II holoenzyme itself. In fact, in human cells the cell cycle arrest that occurs following ectopic expression of BRCA1 appears to be mediated by transactivation of the *p21* promoter. Another gene that is involved in cell cycle regulation, *GADD45*, is also transcriptionally upregulated in response to BRCA1. Finally, BRCA1 also appears to function as a negative transcriptional regulator as it represses estrogen-induced transcriptional activation mediated by the estrogen receptor, ER $\alpha$ .

In summary, the regulation of gene transcription by BRCA1 probably contributes to most or all of its biological activities. This transcriptional regulation occurs through BRCA1 functioning as a coregulator, either by (a) binding to sequence-specific DNA binding transcription factors and stimulating (e.g. p53) or inhibiting (e.g. ER- $\alpha$ ) their activity or (b) through its role as a component of the RNA Pol II complex (modulating basal transcription and/or mediating interactions between sequence-specific transcription factors and the basal transcription factors) (Rosen et al., 2005).

**17.6.1.2 Another Splice Variant of BRCA1.** BRCA1 encodes not only the well-recognized BRCA1-p200 protein, but also a variant that results from alternative splicing—BRCA1-IRIS (“in-frame reading of BRCA1 intron 11 splice variant”) (ElShamy and Livingston, 2004). It is encoded by an alternative exon 1, exons 2–11 and an additional 34 amino acids derived from part of the intron that separates exons 11 and 12. It has a molecular mass of 150kDa and, with a presumably distinct promoter, is expressed in both quiescent and replicating cells, unlike BRCA1-p220, which is expressed only in the latter. BRCA1-IRIS protein is found to be associated with DNA replication origins and is likely to be involved in DNA replication.

**17.6.1.3 Structure and Function of the BRCA2 Protein.** The *BRCA2* gene, which comprises 27 exons, encodes a nuclear protein of 3418 amino acid residues and 384kDa, which is almost twice the size of BRCA1. Like in *BRCA1*, exon 1 is noncoding and exon 11 is

particularly large. With regard to the role of the BRCA2 protein in tumorigenesis, a function in DSB DNA repair appears particularly important. Like the BRCA1 protein, BRCA2 can bind to the DNA recombinase RAD51. Again, the region involved is encoded by exon 11, though in BRCA2 the RAD51-interacting region contains four of the eight copies of a motif of 30–80 amino acids known as the BRC repeat. Furthermore, cells of BRCA2 knockout mice exhibit an increased sensitivity to genotoxic agents but normal apoptotic and cell cycle checkpoint activation, thus further implicating BRCA2 in DNA repair. In the presence of DSBs, BRCA2 binds to RAD51 and it is now known that the complex interacts with the sites of DNA damage with the assistance of a small acidic protein named DSS1 (Gudmundsdottir et al., 2004). Error-free repair takes place by homologous recombination, as is also promoted by BRCA1. The function of RAD51 is to catalyze homologous pairing and DNA strand exchange. BRCA2 is necessary for the delivery of RAD51 protein to the site where it can affect DNA repair. BRCA2 achieves this by physically interacting with both RAD51 and single-stranded DNA, which is exposed following DNA damage (or stalled replication) (Holloman, 2011).

Located at the carboxyl terminus of BRCA2 are three nuclear localization signals, suggesting that disease-causing mutations, which tend to cause truncation upstream of this position, would all result in an abnormal cytoplasmic localization of the mutant protein. At the amino terminus of BRCA2 is a region that interacts with the transcriptional coactivator protein PCAF (p300/CBP-associated factor), which possesses histone acetylase activity. In addition, studies in yeast indicate that the BRCA2 exon 3 product can activate transcription when fused to a DNA-binding domain. Thus, although less well supported than for BRCA1, the crucial normal function of BRCA2 may involve transcriptional regulation in addition to DNA repair and maintenance of genomic integrity.

An interesting paradox is that homozygous BRCA2 truncation, alone, in mice leads to proliferative arrest rather than tumorigenicity. In fact, studies in mice suggested that BRCA2-induced tumorigenesis may require the co-inactivation of one or more cell cycle regulators that normally respond to mitotic spindle disruption, such as the mitotic checkpoint kinases—Bub1 and Mad3L. *BRCA2* is a chromosome instability (*CIN*) gene and it may also regulate cell cleavage and separation (Rudkin and Foulkes, 2005). An important finding in this regard was that cells deficient for BRCA2 (for instance resulting from RNA interference) cannot complete cell division properly, leading to binucleated cells (Daniels et al., 2004). An interesting further observation was that the normal accumulation of myosin II necessary for the cleavage-inducing actinomyosin “contractile ring” was defective. In addition, it colocalizes with the cytokinetic protein, AURORA-B, suggesting that BRCA2 plays an active role in cytokinesis itself. This might explain

the aneuploidy that is frequently detected in *BRCA2*-deficient cells.

**17.6.1.4 *BRCA1* and *BRCA2* Mutations and Cancer Predisposition.** From studies of *BRCA1* mutations in breast cancer patients, many important findings have emerged. By linkage and mutation analyses of nearly 237 families with four or more cases of breast cancer diagnosed before age 60 (or at any age in male cases), germline mutations of *BRCA1* and *BRCA2* were implicated in 52% and 32%, respectively, overall. Moreover, germline *BRCA1* mutations were thought to account for the cancer predisposition in as many as 81% of those families affected by both breast and ovarian cancers (Figure 17-12). In contrast, *BRCA2* mutations were thought to be responsible for ~76% of families in which there is at least one case of male breast cancer.

A sizeable variety of germline mutations in the *BRCA1* gene have been identified and around 95% are predicted to result in the synthesis of a truncated *BRCA1* protein. Most mutations have been identified in only one or two families, but a limited number have been seen recurrently. Of particular note, a population survey of Ashkenazi Jews, selected without regard to family history of cancer, demonstrated that about 1% carry the *BRCA1* 185delAG frameshift mutation. This mutation, or one of the two other Ashkenazi founder mutations, the *BRCA1* 5382insC and the *BRCA2* 6174delT, is found in 2.5% of individuals in this population group. Similarly, 0.6% of Icelanders carry the 999del5 *BRCA2* mutation, which accounts for almost all hereditary breast cancers in Iceland.

Notably, population-based studies of the penetrance of the Ashkenazi founder *BRCA1* mutation 185delAG and the Icelandic founder *BRCA2* mutation 999del5 suggested lower breast cancer penetrances (of 56% and 37% by age 70, respectively) than the previous pedigree-based studies. The differences were likely to be due to the presence or absence of important risk-modifying gene variants, which may well serve to increase the risk when a gene carrier is a member of a family with several affected members. In *BRCA2* mutation carriers, the

ovarian cancer risk is highest for those with mutations located in the “ovarian cancer cluster region” (at nucleotides 3035–6629) of exon 11 (Lubinski et al., 2004).

The use of candidate gene studies and particularly genome-wide association studies (GWAS) has now identified many SNPs that are associated with increased or reduced risk of breast cancer in the general population (~20 SNPs) and act as risk modifiers in *BRCA1* or *BRCA2* mutation carriers (at least 5 and 7 SNPs, respectively). These include SNPs in the *FGFR2*, *CASP8*, *MAP3K1*, *TOX3/TNRC9* and *RAD51* genes (Milne and Antoniou, 2011). Although, generally the SNPs are individually of small effect, they may of course, in combination, exert larger effects.

Surprisingly, very few sporadic tumors have been found to harbor detectable somatic pathogenic mutations in *BRCA1* or *BRCA2*. This has raised questions regarding the role of these genes in sporadic breast and ovarian cancers. Promoter hypermethylation, rather than somatic mutation, may represent an important mechanism by which at least *BRCA1* is inactivated in certain types of sporadic tumors. *BRCA1* promoter hypermethylation has been observed in 67%, 55% and 12% of sporadic medullary, mucinous and ductal breast carcinomas, respectively. In addition, *BRCA1* hypermethylation has been detected in 20% of sporadic ductal breast tumors showing *BRCA1* LOH, suggesting that in these tumors, one allele might be lost by deletion, while the other is silenced by aberrant methylation.

Study of the pathology of sporadic and hereditary breast cancers has revealed some intriguing differences. For instance, the histology of breast cancers in *BRCA1* germline mutation carriers is more often of higher-grade malignancy and more frequently of medullary type than in sporadic cases. In addition, these tumors are more frequently negative for estrogen receptor; progesterone receptors, *ERBB2* (HER2/NEU) (i.e. “triple negative”), are more often positive for p53 overexpression (Narod and Offit, 2005), and often show a “basal-like” gene expression profile (Foulkes et al., 2010). So-called

FIGURE 17-12

“basal-like” phenotype refers to the expression of high molecular weight (i.e. basal) cytokeratins (cytokeratins 5, 14 and 17), lower levels of p27, and higher levels of cyclin E, caveolins 1 and 2 and caspase 3.

Triple negative breast tumors and basal-like breast cancers generally have a poorer prognosis (Foulkes et al., 2010). No specific biological therapy is currently available and chemotherapy is usually chosen. Nevertheless, some of these tumors will be deficient in BRCA1 pathway function. This is important as these tumors may be sensitive to poly (adenosine diphosphate-ribose) polymerase (PARP) inhibitors. These inhibitors target cells that lack normally functioning homologous recombination DNA repair by inhibiting the enzyme that mediates base-excision repair. Blocking the latter type of repair leads to unrepaired single-strand breaks, stalled DNA replication forks and ultimately, possibly the production of DSBs that are then lethal to these cells (Hewish et al., 2010). PARP inhibitors (such as olaparib) have in fact been found to yield encouraging results when used in trials to treat tumors arising in BRCA mutation carriers as well as sporadic triple-negative cancers (Foulkes et al., 2010).

### 17.6.2 FANCD1/BRCA2

It is known that *BRCA2* is the Fanconi anemia complementation group D1 gene. Thus, biallelic *BRCA2* mutations have been detected in the cells of patients with this autosomal recessive condition. Monoallelic mutations in other Fanconi anemia genes, however, appear from mutation analyses in familial breast cancer patients of *FANCA*, *FANCC*, *FANCD2*, *FANCE*, *FANCF*, and *FANCG*, unlikely to frequently underlie high-penetrance breast cancer predisposition. Together with RAD51, *BRCA2* probably acts downstream of the other Fanconi anemia proteins in the Fanconi anemia DNA repair pathway since, in cells deficient in *BRCA2*, the core Fanconi anemia protein complex is unaffected and still results in *FANCD2* ubiquitination.

### 17.6.3 Hereditary Non-Polyposis Colorectal Cancer and Mismatch Repair

Familial clustering of CRC has long been noted. In fact, a genetic component is likely to be a primary factor in at least 10% of CRC cases. HNPCC probably accounts for about 5–8% of all CRC patients. At least 10-fold less frequent than HNPCC is the familial adenomatous polyposis, which, as reviewed above, is a rare syndrome (with an approximate incidence of 1 in 10,000) that results from germline mutations in the *APC* gene. MAP is a more recently described autosomal recessive syndrome with a phenotype similar to that of attenuated familial adenomatous polyposis.

The diagnosis of the HNPCC syndromes on a clinical basis alone is problematic for two reasons. First, for

a common malignancy like CRC, there is a likelihood of clustering within families by chance. Second, there is a lack of overt premalignant clinical characteristics, such as polyposis. Nevertheless, strict diagnostic criteria for HNPCC have been published, the Amsterdam criteria II: (1) exclusion of familial polyposis in the CRC cases, if any, and verification of tumor types by pathological examination; (2) HNPCC-associated cancer in at least three relatives, one of them being a first-degree relative of the other two; (3) two or more successive generations affected; and, in addition, (4) at least one of the affected individuals should be less than 50 years of age at the time of diagnosis. For these strict criteria, the “HNPCC-associated cancer” was defined as cancer of the colon or rectum, the endometrium, small bowel, ureter, or renal pelvis. These tumors were considered to be the most specific for HNPCC, having the highest relative risks. It was acknowledged, however, that gastric, ovarian, brain, hepatobiliary and sebaceous skin tumors are also associated with the syndrome, despite not being included in the Amsterdam criteria II. These criteria represented a modification (by the International Collaborative Group on HNPCC) of the original “Amsterdam” criteria, in which only CRCs were included. Nevertheless, the modified criteria remain relatively strict and are designed primarily as selection criteria for collaborative studies. They were not intended to serve as a guide for the exclusion of suspected families from genetic counseling and mutation analysis. In addition to the Amsterdam criteria and their modifications, the Revised Bethesda Guidelines (Umar et al., 2004a, 2004b) were developed, though principally with the aim of selecting tumors for testing for mismatch repair deficiency. The attempts that have been made to improve on these guidelines included mutation analysis for the *BRAF* V600E mutation and *MLH1* methylation analysis (Hewish et al., 2010). A fairly comprehensive practical review of clinical management guidelines for CRC screening in moderate and high risk groups has been published recently (Cairns et al., 2010).

The HNPCC kindreds were often previously categorized as either Lynch syndrome I (CRC only) or Lynch syndrome II (colorectal and other tumors). The more inclusive term HNPCC is often used now to encompass both syndromes and distinguishes them from the polyposis syndromes. In HNPCC, compared to sporadic cases, the CRCs show a predilection for the proximal colon, a tendency to be of mucinous type with a lymphoid aggregation at the tumor margin, and, on immunohistochemistry, to exhibit loss of *MLH1*, *MSH2*, or *MSH6* protein expression. Furthermore, the adenomas that occur in HNPCC have been reported to be larger, have a villous growth pattern, and tend to be more dysplastic than those arising in the general population.

**17.6.3.1 Genes Responsible for HNPCC.** Studies from the mid-1980s attempted to localize the genes responsible for HNPCC. No evidence was obtained to link the

HNPCC syndrome to any known TSGs (such as *APC*, *TP53*, or *RB1*). Thus, a search of the entire genome for the HNPCC gene(s) was carried out. Several different genes responsible for the HNPCC syndromes have since been identified, predominantly by linkage analysis of large kindreds, including a gene at chromosome 2p16 (*MSH2* or *hMSH2*) and one at chromosome 3p21 (*MLH1* or *hMLH1*) that together account for the majority of HNPCC cases. Based on studies of highly related genes from bacteria and yeast, the protein products of the *MSH2* and *MLH1* genes (homologs of the bacterial mismatch repair enzymes MutS and MutL, respectively) were predicted to be involved in the recognition and repair of DNA mismatches in humans. Additional mismatch repair (*MMR*) genes have been identified, the MutL homologs, *PMS1* and *PMS2*, and two MutS homologs, *MSH6* and *MSH3*, which both encode proteins that heterodimerize with *MSH2*.

Approximately 50% of those families who satisfy the original Amsterdam criteria have mutations in either *MLH1* or *MSH2* genes with mutations in *PMS1*, *PMS2*, or *MSH6* (also known as *GTBP*) being detected much less frequently. In contrast to germline mutations in *MLH1*, 49% of which are nonsense or frameshift, 83% of germline mutations in *MSH2* are truncating. Moreover, large genomic deletions are common in *MSH2* (10–20% of all mutations) but are less common in *MLH1* and rare in *MSH6* (de la Chapelle, 2004). They generally arise through *Alu* repeat-mediated homologous recombination (Van der Klift et al., 2005). Mutations in *MMR* genes are listed in the database of the International Society for Gastrointestinal Hereditary Tumors (InSiGHT), which is accessible online at <http://www.insight-group.org>.

It is estimated that a deficiency of mismatch repair is present in 15–17% of all primary CRCs (Hewish et al., 2010). In fact, for very early-onset CRC (<30 years), unselected for family history, as many as 28% of patients possess a germline mutation in an *MMR* gene. In these early onset cases, the determination of replication error (RER) status by screening for microsatellite instability (MSI) (the accumulation of different-sized alleles of microsatellite sequences in tumor DNA) appears to be useful in predicting the presence of a germline mutation in an *MMR* gene. The positive predictive value of the analysis in one study was 63%, with a sensitivity of 12/14 cases (86%).

Germline deletions affecting the 3' end of the *EpcAM* gene that result in transcriptional read-through and consequent hypermethylation (and transcriptional silencing) of *MSH2* have been observed. In fact, these deletions and incidences of germline *MLH1* hypermethylation together account for as many as 16% of “genetically proven Lynch syndrome cases” (Niessen et al., 2009a, 2009b). The *EpcAM* gene encodes the epithelial cell adhesion molecule.

Interestingly, mutations in *PMS2* can cause an autosomal recessive childhood cancer syndrome consisting of supratentorial primitive neuroectodermal tumor (PNET),

together with café-au-lait patches, rather than classical early-onset HNPCC (De Vos et al., 2004). Moreover, as a consequence of the discovery of a transcribed close paralog of the *PMS2* gene, *PMS2CL*, in addition to the nontranscribed *PMS2* pseudogenes, there is a growing possibility that mutations in *PMS2* are less rare than previously suggested, on account of detection difficulties resulting from the presence of these other sequences (De Vos et al., 2004; Nakagawa et al., 2004).

Dominantly inherited CRC phenotypes resembling HNPCC have also been found to be associated with germline mutations in a few non-*MMR* genes such as *AXIN2* (Lammi et al., 2004), *TGFBetaR2* and *POLD*. Interestingly, *AXIN2* encodes a protein involved in the WNT/APC signaling pathway and is somatically mutated in some sporadic CRCs.

A few founder mutations associated with HNPCC have now been described. These include an *MSH2* intron 5 splice donor-site mutation that leads to transcriptional skipping of exon 5 and the loss of *MSH2* expression, and is believed to account for 5–10% of all HNPCC-associated germline mutations worldwide (de la Chapelle, 2004). This mutation, a founder mutation in Newfoundland, in fact arises de novo in most cases and occurs in a stretch of 26 adenines, probably creating a DNA polymerase slippage hotspot (de la Chapelle, 2004). Other founder mutations include an *MLH1* exon 16 deletion that accounts for over 50% of HNPCC cases in Finns, an *MSH2* Ala636Pro substitution in Ashkenazi Jews (Foulkes et al., 2002), and an *MSH2* exons 1–6 deletion in North Americans (Lynch et al., 2004) believed to have been introduced into North America in 1727 by an immigrant from Germany (de la Chapelle, 2004).

Although MSI is present in cancers in nearly all patients with HNPCC, in sporadic CRC cases, in general, MSI is observed in only 10–15%. In these sporadic tumors with MSI, however, somatic mutations in *MMR* genes are found in only around 25%. The most common mechanism of somatic *MMR* gene inactivation in at least sporadic endometrial and gastric cancers with MSI, in contrast, is hypermethylation of the CpG island at the *MLH1* promoter, followed by the loss or hypermethylation of the second allele.

**17.6.3.2 The Mismatch Repair System.** The roles of the protein products of the genes involved in HNPCC have been determined. Mismatched bases, usually arising from replication errors, are initially recognized by a complex of two MutS-related proteins. Generally, single-base mismatches are recognized by a MutS alpha heterodimer consisting of *MSH2*/*MSH6*, while insertion/deletion loops are recognized by *MSH2*/*MSH3* (MutS beta). The DNA-bound MutS heterodimer subsequently interacts with a heterodimeric complex of MutL-related proteins (*MLH1*/*PMS1* or *MLH1*/*PMS2*). Following the assembly of this large protein complex, a portion of the DNA strand containing the mismatched base is excised

by an exonuclease that proceeds from a “nick” made up to 2kb from the mismatch. Finally, the excised tract is repaired with correctly pairing bases by DNA polymerase delta.

Interestingly, patients with HNPCC whose tumors show no or mild MSI (i.e. “MSI-low”) often possess germline *MSH6* mutations. This finding presumably reflects the predominant involvement of *MSH6* in repair of mismatches, rather than of the insertion/deletion events that give rise to MSI. An important implication of this finding is that when HNPCC is suspected, absence of MSI does not completely exclude the possibility that an MMR gene mutation is present.

In cells with one normal and one mutant allele of a DNA mismatch repair gene, DNA repair is not, for the most part, impaired. Inactivation of the remaining normal allele can occur as a result of a somatic event, usually allelic loss, in an initiated cell population during tumor development. Once the cell loses this vital component of its self-protection mechanism, it acquires a so-called “mutator phenotype.” Many errors may then arise and fail to be repaired during each cell division. Complete inactivation of an MMR gene may, therefore, promote tumorigenesis through a failure to recognize and repair the multiple point mutations that arise subsequently. Although many of these mutations may be detrimental to cell growth and survival, a subset of the mutations is likely to activate oncogenes or inactivate other TSGs. For instance, genes that have been identified as being frequently mutated in tumors with an MMR defect include those encoding the transforming growth factor beta type II receptor, the E2F4 transcription factor the IGF-II receptor, PTEN and the BAX proapoptotic protein.

**17.6.3.3 Cancer Predisposition in MMR Gene Mutation Carriers.** As mentioned above, in addition to CRC, HNPCC mutation carriers are at a significantly increased risk of other cancers. A study of 360 Finnish mutation carriers found them to have a significantly increased risk of colorectal (standardized incidence ratio (SIR) of 68, with a cumulative incidence of 82% by age 70), endometrial (SIR 62, 60% in women), ovarian (SIR 13, 12% in women), biliary tract (SIR 9.1, 2.0%), bladder/ureter/urethra (SIR 7.6, 4.0%), gastric (SIR 6.9, 13%), kidney (SIR 4.7, 3.3%) and CNS (SIR 4.5, 3.7%) cancers. The ovarian cancers were predominantly cystadenocarcinomas, while the CNS tumors were most commonly glioblastoma multiforme. Only four breast cancers occurred, with an SIR of 1.4 that was not statistically significant. The 360 carriers were from 50 families, most of whom possessed the same *MLH1* mutation and only three had an *MSH2* mutation. Interestingly in females, by age 70, the incidence of endometrial cancer (60%) exceeded that of CRC (54%), while in men, the incidence of CRC was said to be 100%. These figures were thus higher than those of Dunlop et al. (1997) who, studying 67 mutation carriers (predominantly of

*MSH2*), found that the incidences of endometrial cancer and CRC in females (by age 70) were 42% and 30%, respectively, while the incidence of the latter in males was 74%.

**17.6.3.4 Predisposition to Colorectal Cancer by Low Penetrance Genes.** Many apparently familial CRCs that are not due to FAP or HNPCC, may be predisposed to by low-penetrance gene mutations or polymorphisms. An example of the latter is the polymorphism in the *APC* gene, the T to A transversion at nucleotide 3920, which results in the substitution of a lysine in place of an isoleucine at codon 1307 (I1307K). More importantly, it creates a small hypermutable region of the gene, by converting an AAATAAAA sequence to an AAAAAAAA sequence, which is then susceptible to a single adenine insertion or deletion. This founder polymorphism, which is found mainly in Ashkenazi Jews (with a heterozygote frequency of 5–7%), appears to be associated with a relative risk of CRC of between 1.5 and 2.2 with wide confidence limits, and corresponding attributable risk in this population of between 3 and 7% (de la Chapelle, 2004).

It is now apparent that in Caucasian populations, an Ala-repeat polymorphism (6Ala) in the coding region of the antiproliferative *TGFbetaR1* gene is present in ~14% of individuals and is associated (in heterozygotes) with a relative risk of 1.14 of colon cancer, as calculated in a meta-analysis (Pasche et al., 2004). This polymorphism was also calculated to predispose to breast and ovarian cancers with relative risks in heterozygotes of 1.34 and 1.29, respectively (Pasche et al., 2004).

In a large study aiming to identify modifier genes for HNPCC, 6 SNPs originally identified in a large GWAS of unselected CRCs were analyzed in CRC families. Only two of them (at 8q23.3 and at 11q23.1) proved to be significantly associated with tumor development in HNPCC mutation carriers (Antoniou and Chenevix-Trench, 2010).

## 17.6.4 Emerging Therapeutic Possibilities for MMR Deficiency

Several different therapeutic approaches are being investigated as ways of selectively targeting MMR deficient cells. Drugs that cause oxidative damage, including methotrexate, have been observed to be selectively lethal to *MSH2*-deficient tumor cells. This was found to be accompanied by an accumulation of the oxidative stress-associated DNA lesion, 8-OHdG (Martin et al., 2009). Clinical studies of methotrexate in patients with *MSH2*-deficient metastatic CRC are currently underway.

Other approaches include the targeted inhibition of the protein products of oncogenes that frequently acquire secondary (activating) mutations as a consequence of the mutator phenotype (that occurs as a result of MMR deficiency). For instance, inhibitors of the PI3K/mTOR pathway are being investigated (Vilar et al., 2009).

Inhibition of PARP has been found to be a promising new therapy for the treatment of BRCA1- and BRCA2-deficient breast and ovarian cancers. PARP inhibition may also prove useful for some MMR-deficient tumors in the future, in view of the secondary mutations that occur in genes (such as *MRE11* and *hRAD50*) that encode components of the DSB repair mechanism (Hewish et al., 2010).

It is likely that, in the future, the selection of a therapy for MMR-deficient tumors will depend on the precise primary and secondary tumorigenic mutations that have occurred.

### 17.6.5 *MutYH/MYH*-Associated Polyposis

MAP is an autosomal recessive colorectal adenoma and carcinoma predisposition syndrome with phenotypes very similar to FAP and attenuated FAP. This important novel syndrome results from biallelic inherited mutations in a BER gene *MutYH* (human MutY homolog, also commonly known as *MYH*) in the absence of inherited mutations in the *APC* gene.

The condition was initially identified as a result of the investigation of a family in which three out of seven siblings appeared to have attenuated FAP, but without any detectable inherited truncating mutation in *APC* (Al-Tassan et al., 2002). Further analyses revealed somatic mutations in the *APC* gene in the colorectal tumors, which were mostly G:C to T:A transversions. This type of mutation was already known to result from defects in the specific BER pathway that normally corrects mutations that are related to 7,8-dihydro-8-oxo-guanine (8-oxoG). This, the most stable product of oxidative DNA damage, is highly mutagenic on account of its ability to mispair with adenine residues, therefore resulting in spontaneous G:C to T:A transversion mutations in cells deficient in the necessary BER mechanism. Consequently, mutation analysis was carried out on the genes, *MutYH* (*MYH*), *OGG1* and *MTH1*, which encode the proteins involved in this type of DNA repair. This subsequently led to the discovery of missense germline mutations in both alleles of *MutYH* in each of the affected siblings. Colonoscopies of the siblings that were heterozygous for either of the mutations were normal. *MutYH* is a DNA glycosylase that normally removes adenines that have been misincorporated into DNA as a result of pairing with an 8-oxoG residue.

A variety of different mutations have been identified in individuals with MAP. The two mutations detected in the affected siblings were Y165C and G382D, which are the most common mutations in the *MutYH* gene in northern Europeans, by far. In fact, these mutations, which are now known as Y165C and G396D, are present in 1–2% of North Americans and northern European populations (Jones et al., 2009). The functional consequence of these mutations has been verified in vitro and they have been shown to result in reduced DNA glycosylase activity. A

few other recurrent mutations have been detected in specific populations such as the 1395delGGA mutation in Italians (Gismondi et al., 2004). Truncating mutations have been found throughout the coding sequence while non-truncating mutations tend to cluster in the functional domains (Sampson et al., 2005).

In general, biallelic *MutYH* mutations have been detected in around 25% of patients with phenotypes like FAP or attenuate FAP but in whom no germline *APC* mutations have been found (Gismondi et al., 2004; Sampson et al., 2005; Isidro et al., 2004; Venesio et al., 2004; Eliason et al., 2005). Biallelic *MutYH* mutations appear to impart an excess risk of CRC of 93-fold with almost complete penetrance by the age of 60 (Farrington et al., 2005). The number of adenomas can be less than 10 and in several cases CRC has even developed in the apparent absence of any obvious polyposis (Sampson et al., 2005; Croitoru et al., 2004). The phenotype has been found to be more severe in those patients with homozygosity for the Y179C mutation than those who are homozygous for the G396D mutation (or who are compound heterozygotes) (Nielsen et al., 2009a, 2009b).

Identification of those patients with MAP and biallelic *MutYH* mutations facilitates the appropriate testing and surveillance of the appropriate family members, particularly the siblings of MAP patients. A very recently reported longitudinal study of 492 patients on the Manchester Polyposis Registry has found that those individuals who possess biallelic *MutYH* mutations have a median survival of 69.7 years (Newton et al., in press). Duodenal adenomas have been reported in MAP patients (Sampson et al., 2005) and a European study has found that individuals with MAP have a lifetime risk of duodenal cancer of 4% (Vogt et al., 2009). In addition, a significantly increased incidence of ovarian, bladder, and skin cancers (standardized incidence ratios of 5.7, 7.2, and 2.8, respectively) was observed (Vogt et al., 2009).

An additional important question has been whether there is any clinically significant increase in the risk of CRC in individuals who are *MutYH* heterozygotes. Early data from a very large study (2239 cases and 1845 controls) suggested that if there is such an increased risk it is likely to be relatively small and possibly only related to late-onset disease (Farrington et al., 2005). A subsequent, retrospective, study of ~350 parents of patients with MAP (and matched controls) has found that there is a modest increase in risk of CRC of approximately 2-fold but with no significantly increased CRC-related mortality (Jones et al., 2004). The authors noted that this increased risk was comparable to the relative risk observed in the individuals in the general population who are first-degree relatives of patients who have sporadic CRC. They therefore suggest that colorectal screening in heterozygous carriers of a *MutYH* mutation need not be more intensive than in that group (Jones et al., 2004). There is some evidence that the mechanism by

which CRC may occasionally occur in *MutYH* carriers may involve loss of heterozygosity.

With regard to the molecular changes within the tumors developing in MAP, MSI is not usually present (Al-Tassan et al., 2002). There is, in addition, no evidence of mutations in *BRAF*, *SMAD4*, or *TGF-beta* but in some MAP adenomas there is an unusual activating missense mutation of K-RAS, G12C, that results from a G to T transversion (Jones et al., 2004). In addition, in contrast to the MMR genes and particularly the *APC* gene, *MutYH* is not often somatically inactivated by mutation or epigenetic silencing in sporadic colorectal tumors. There is some evidence, however, that BER cooperates with the MMR system in preventing 8-oxoG-mediated mutagenesis. In fact, earlier biochemical analyses established that *MutYH* can bind directly to MSH6, resulting in increased glycosylase activity of *MutYH*.

The study by Fleischmann et al. evaluated whether germline *MutYH* mutations accounted for a significant proportion of early-onset CRCs in general (Fleischmann et al., 2004). Peripheral blood lymphocyte DNA samples from a total of 358 CRC patients in whom CRC had been diagnosed before the age of 56 (but otherwise unselected for phenotype or family history) were screened for germline changes in the gene. Only two cases (0.6%), however, were found to have biallelic *MutYH* mutations and it was concluded that biallelic *MutYH* mutations were unlikely to account for more than 3% of early-onset CRC. Additional data, consistent with this, have been reported (Farrington et al., 2005) indicating that biallelic pathogenic *MutYH* mutations were detected in only 1 out of 50 patients who were diagnosed with CRC aged under 40 years and in just 1 out of 150 patients diagnosed under 55 years of age.

A recent report suggests that *MutYH* polyposis can, in some cases, result from the additive effects of mutations in different genes that encode components of the same (base excision) DNA repair pathway (Morak et al., 2011). Specifically, a patient with CRC and adenomas at age 36 was found to be a double heterozygote for a *MutYH* missense mutation and an *OGG1* mutation that affects splicing of exon 1. The *OGG1* gene encodes 8-oxo-guanine DNA glycosylase. The *MutYH* mutation, p.Ile223Val, alters an amino acid located in the helix-hairpin-helix domain, and was classified by the authors as possibly pathogenic despite the structural similarity of Ile and Val. The splicing effect of the novel *OGG1* (p.Arg46Gln) mutation was confirmed by cDNA analysis (Morak et al., 2011). Further studies will be required to confirm the conclusions from this study.

### 17.6.6 Ataxia Telangiectasia (and the Role of ATM in DNA Double-Strand Break Repair)

Ataxia telangiectasia (AT) is an autosomal recessive disorder primarily affecting the central nervous and

immune systems. The condition is characterized by cerebellar degeneration, immunodeficiency, radiation sensitivity, cell cycle abnormalities, chromosomal instability, and a striking predisposition to leukaemias and lymphomas. For many years, there have been conflicting findings regarding whether heterozygosity for an AT mutation confers an increased risk of breast cancer. A large study, of 1160 relatives of patients with AT, did indicate a moderately increased risk of breast cancer in AT mutation carriers. The relative risk, compared to the general population, of breast cancer in carriers was 2.23 overall and 4.94 in those younger than age 50 years (Thompson et al., 2005). Truncating and non-truncating mutations were not found to be associated with significantly different relative risks (Thompson et al., 2005). More recently, in silico analyses of *ATM* missense mutations have been used to evaluate the frequency of occurrence of such mutations in evolutionarily conserved regions of the gene in breast cancer patients and in controls (Tavtigian et al., 2009). They found that those missense mutations that are predicted by algorithms to be deleterious to the protein's function were associated with breast cancer risk, which was even higher than the risk found to be associated with truncating or splice-site mutations. This finding would suggest a dominant negative effect. It is now regarded that the *ATM* gene, like *CHEK2*, *PALB2* (Partner and localizer of BRCA2) and *BRIP1* (BRCA1-interacting protein 1), is an intermediate penetrance gene for breast cancer, conferring, overall, a 2–3-fold increased risk of breast cancer (Shuen and Foulkes, 2011).

Originally, AT was thought to be genetically heterogeneous, with four complementation groups attributed to different genes. Using positional cloning strategies, *ATM* (for AT, mutated), the gene on chromosome 11q responsible for AT, was identified. Surprisingly, *ATM* was found to be mutated in the germline of patients from all four complementation groups, indicating that it was the sole gene responsible for this disorder. The *ATM* gene, which possesses 66 exons and is located at 11q22-23, is widely expressed and has a transcript size of 12 kb. It encodes a protein of 350 kDa exhibiting similarity, through a kinase domain located in its C-terminal region, to several yeast and mammalian phosphatidylinositol-3 kinases involved in DNA damage recognition and cell cycle control. Its kinase domain, however, possesses protein, rather than phospholipid, kinase activity. *ATM*'s activity increases dramatically within minutes following DSBs such as those induced by ionizing radiation and its activation is believed to be associated with its conversion to an active monomer from an inactive homodimeric state in which the kinase domain of each *ATM* molecule is blocked by the FAT domain of another (Ball and Xiao, 2005). The activation of *ATM* is only partially understood, but it involves auto- or trans-phosphorylation of serine-1981 in response to DNA DSBs and may require protein phosphatase 5 activity (Kurose et al., 2005; Ali et al., 2004). The intriguing

question of how a few breaks in the genome can lead rapidly to the activation of the entire nuclear ATM pool might therefore be answered if a chain reaction occurs, involving released active ATM monomers phosphorylating inactive ATM dimers.

Phosphorylation of *TP53* directly by ATM occurs on Ser15. However, although this direct phosphorylation is critical for the apoptotic activity of *TP53*, the mechanism by which stabilization of *TP53* is induced by ATM is indirect. It occurs by ATM's activation of CHK2/hCds1, which, in turn, phosphorylates *TP53* on Ser20 preventing *TP53*'s degradation by MDM2 (Figure 17-8). In addition to this role in inducing cell-cycle arrest following DNA damage, ATM is implicated in signaling to the repair machinery. For instance, in response to DSBs, it appears to be required for the activation of both the BRCA1–RAD51 complex and the NIBRIN–MRE11–RAD50 complex (see Section “Nijmegen breakage syndrome”). Finally, the autophosphorylation of ATM may be necessary but not sufficient to activate the cellular DNA damage response, merely priming the cells to respond to DNA damage.

### 17.6.7 Bloom Syndrome, Werner Syndrome and Rec-q Helicases

The disorders (BS, WS and Rothmund–Thomson syndrome) that result from defects in the genes encoding the RecQ helicase proteins generally cause premature aging and a predisposition to cancer.

BS is a progressive autosomal recessive disorder characterized by small stature, sun sensitivity, immunodeficiency, chromosome instability, and a striking predisposition to cancer. Cells from patients with BS show an approximate 10-fold increase in the frequency of sister chromatid exchanges (SCEs), which arise by crossing over of chromatid arms during homologous recombination. *BLM*, the gene responsible for BS, was identified by “somatic crossover point mapping” and encodes a 1417 amino acid residue protein with homology to the bacterial RecQ helicases, proteins that can unwind double-stranded DNA into single-stranded DNAs and are believed to possess a role in DNA repair and/or replication. The BLM protein contains seven conserved helicase motifs and appears to exist as a hexameric ring structure surrounding a central hollow. It interacts with RAD51 recombinase and together with topoisomerase III $\alpha$  can resolve double Holliday junctions. Like the WS protein (see below), it thus recognizes and unwinds a wide variety of different DNA structures that arise during homologous recombination DNA repair. Although crossing over is required in meiosis and in the repair of DSBs, in mitotic cells it can be associated with detrimental loss of heterozygosity. BLM is believed to prevent excessive crossing over with BLM inactivation therefore resulting in hyper-recombination and thus SCEs and genomic instability. It also catalyzes the annealing of DNA single strands and it may be involved in the

resolution of DNA structures occurring in the late stages of DNA replication; for example, where two replication forks converge (Cheok et al., 2005). The physiological role of BLM in human cells remains to be fully determined but it is widely believed that the protein plays an important part in restarting blocked DNA replication forks (Chabosseau et al., 2011).

Werner syndrome is a rare autosomal recessive disorder characterized by premature aging, with an early onset of age-related diseases such as atherosclerosis and, in addition, tumors such as soft-tissue sarcomas. The causative gene, *WRN*, has been identified and its function studied. Like the BS gene, it encodes an ATP-dependent DNA helicase, with 3'–5' directionality, homologous to the *E. coli* protein RecQ and which unwinds double-stranded DNA. The WRN protein has been found to interact with numerous proteins including DNA replication proteins, such as the multifunctional replication protein A (RPA), PCNA, topoisomerase I, DNA polymerase delta and FEN1 (Ozgenç and Loeb, 2005). It also interacts with DNA repair proteins such as *TP53*, PARP-1, DNA polymerase beta, APE-1 and the Ku-DNA-PK complex (Ozgenç and Loeb, 2005). In addition, consistent with the observed premature replicative senescence and increased loss of telomeres in WS cells, WRN has been found to associate with the telomere repeat binding factors: TRF1 and TRF2 (Opresko et al., 2004; Machwe et al., 2004). In addition to helicase and ATPase activities, the WRN protein, unlike other RecQ helicases, possesses a 3'–5' exonuclease function. Cells from WS patients, unlike those from BS patients, do not typically show increased SCEs, though both groups of cells do exhibit genomic instability. WS cells also exhibit defects in DNA replication, recombination, repair and transcription (Kyng and Bohr, 2005). The importance of WRN in vivo, however, especially in relation to WS, has not yet been defined precisely, but most likely involves the participation of WRN in the resolution of alternative DNA structures thought to exist as intermediates in a variety of DNA synthetic processes. These processes include DNA replication (forked DNA), repair (e.g. partial duplexes with a single-stranded bubble), recombination (triplex DNA, G4 tetraplexes and Holliday junctions) and telomere maintenance (D-loops). Recently, a small molecule inhibitor of WRN helicase activity, without inhibiting the other DNA helicases, has been identified from the US National Cancer Institute's Diversity Set (Aggarwal et al., 2011).

In addition, patients with Rothmund–Thomson syndrome, a further rare autosomal recessive disorder associated with genomic instability, premature aging and a predisposition to neoplasia, have been found to have mutations in another RecQ helicase gene, *RECQL4*. The RECQL4 protein has been found to localize to distinct nuclear foci and to associate with RAD51, thus implicating it in the repair of DNA DSBs by homologous recombination (Petkovic et al., 2005). Although the

precise function of RECQL4 is not yet fully understood, a general consensus is that it is involved in DNA repair and the most recent data indicate that it is the N-terminal region so the protein that is most important for its normal function (Abe et al., 2011).

### 17.6.8 Nijmegen Breakage Syndrome

Nijmegen breakage syndrome is another rare autosomal recessive DNA repair disorder. Like in both AT and BS, there is chromosomal instability, immunodeficiency, and a predisposition to cancer. In NBS, there is a highly increased risk of lymphoreticular malignancy (Seemanova et al., 2005). Unlike in AT, however, specific neurological features are rare, and the serum alpha-fetoprotein is not raised. In addition to those features mentioned above, microcephaly with relatively preserved mental development, typical facial appearance, growth retardation and X-ray hypersensitivity are characteristic, with café-au-lait spots, vitiligo, clinodactyly and syndactyly being additional important features. The SCEs, characteristic of BS, are not, however, a feature of either AT or NBS. The first patient with NBS was not described in 1981 and the defective gene, *NBS1*, was identified in 1998. *NBS1* is located on chromosome 8q21 and encodes a protein named NIBRIN. Sequence analysis revealed two amino terminal domains, a forkhead associated domain (FHA) and a breast cancer carboxy terminal domain (BRCT), both of which had previously been found in DNA damage responsive cell cycle checkpoint proteins. Further evidence for the role of NIBRIN in the repair of DNA damage was provided by the finding that it forms a heterotrimeric complex with MRE11 and RAD50, which participate in DSB DNA repair. This complex is recruited to DSB sites to process the DNA in preparation for repair. It appears that MRE11, by virtue of its exonuclease activity, prepares the ends of the DNA for repair and that RAD50 holds the ends together (Stracker et al., 2004).

The similarity between the chromosomal instability observed in at least AT and NBS can now be partly explained at the protein level. The protein kinase, ATM, which is activated by DSBs, is now known to phosphorylate not only p53, CHK2, and BRCA1, but also NIBRIN. Phosphorylation of NIBRIN by ATM occurs at four sites—serine residues 278, 343, 397 and 615—and the phosphorylation of all four appears necessary for the cellular response to DNA damage. Thus, in the presence of damaged DNA, ATM normally functions not only by activating cell-cycle checkpoints (by phosphorylating CHK2 and p53) and thus preventing duplication of damaged DNA but also by activating the repair of the damage. Studies using Nbs1 mouse models indicated that nibrin acts not only downstream of ATM but also upstream of ATM, forming a positive feedback or amplification loop that permits a small number of DNA DSBs

to generate a potent checkpoint response (Diflippantonio et al., 2005).

Over 90% of patients with NBS have been found to possess a founder truncating 5bp *NBS1* deletion, 657–661 delACAAA, which results in the production of a 26 kDa protein that lacks the MRE11-binding domain (Ball and Xiao, 2005). Most patients are of Slavic origin and are homozygous for this 657del5 mutation (Seemanova et al., 2005). Monozygotic twin brothers, compound heterozygous for 657del5 and a 643C>T(R215W) mutation, were reported to be more severely affected than the majority of NBS patients, with severe developmental delay, that is unusual in NBS patients (Seemanova et al., 2005). Accordingly, their cells displayed strongly reduced phosphorylation of ATM and p53.

### 17.6.9 Xeroderma Pigmentosum and Nucleotide Excision Repair

Xeroderma pigmentosum (XP) is one of three rare recessive syndromes with significant cutaneous photosensitivity (XP, Cockayne syndrome and the photosensitive form of trichothiodystrophy) that results from a defect in the nucleotide excision repair (NER) DNA repair mechanism. The role of NER is to remove helix-distorting bulky adducts, such as the UV-induced cyclobutane pyrimidine dimer (CPD) formed between adjacent pyrimidines in the same DNA strand. The cutaneous hallmarks of XP are “parchment skin” and prominent freckles on the sun-exposed areas of skin. Moreover, XP patients have an ~1000-fold increased risk of skin cancer, predominantly basal cell and squamous cell carcinomas, with melanomas occurring less frequently. The mean age of onset of skin tumors is 8 years. Patients with CS or trichothiodystrophy (TTD), in contrast, have not been demonstrated to possess an increased risk of skin cancer. Cockayne syndrome (CS), in addition to cutaneous photosensitivity, comprises a growth defect, cataracts, progressive neurological degeneration, microcephaly, sensorineural hearing loss, pigmentary retinopathy and dental caries. TTD is a complex neuroectodermal disorder that involves a deficiency in the synthesis of high-sulfur matrix proteins and comprises sulfur-deficient brittle hair, cutaneous photosensitivity, growth retardation, intellectual impairment and other features such as ichthyosis and neutropenia.

Cell fusion and molecular studies have defined eight genes (initially differentiated as complementation groups) for XP (*XPA* to *XPG*; *XPV*), two for CS (*CSA* and *CSB*), and three for TTD (*XPB*, *XPD* and *TFB5*) that have been cloned and the function of their products has been partly determined. There are two tightly regulated NER pathways, together involving a total of around 40 proteins, and both can be affected in XP: global genome repair (GGR) and the less widespread (but often more rapid) transcription-coupled repair (TCR). In general, NER

proceeds by the following steps: (a) initial DNA damage recognition (involving XP-C and XP-E in GGR, and CS-A and CS-B together with a stalled RNA polymerase in TCR); (b) local chromatin unwinding (involving the zinc-finger protein, XP-A, and the two helicase subunits of the transcription initiation factor TFIIH, XP-B and XP-D); (c) excision of 24–32 nucleotides of the damaged strand by incisions made at sites flanking the lesion (by the 5' and 3' endonucleases XP-F and XP-G); and finally (d) gap filling by DNA polymerase delta, PCNA and DNA ligase (Cleaver, 2005).

Many patients in the XP-A, XP-B, XP-D, and XP-G groups (in which, typically, both TCR and GGR NER activities are deficient) tend to have more severe NER deficiencies, while patients in the XP-C and XP-E groups (who have deficient GGR but not TCR) and in the XP-F group tend to have either absent or late-onset neurological symptoms. The absence of cancer predisposition in patients with CS might be related to the role of CS-A and CS-B in mediating only the initial damage recognition step of transcription coupled repair. It has been suggested that the failure to carry out TCR, specifically, would lead to increased apoptosis and consequent neuronal loss rather than a high degree of genomic instability, copy number changes and cancer predisposition. Genomic instability would instead be envisaged to be a feature in patients with mutations affecting the XP genes encoding proteins involved in either GGR initiation specifically or even within the common part of the pathway (i.e. steps subsequent to the initial recognition step). Inactivation of XP proteins within the common part of the pathway would also be predicted to predominantly affect GGR rather than TCR, since only around 1–2% of total genomic DNA is estimated to be actively transcribed (Cleaver, 2005). Similarly, those patients whose mutations affect proteins that are not involved in TCR (i.e. XP-C, XP-E and XP-V) have fewest non-cancer disease manifestations and rarely have significant neurodegenerative disorders. Patients with mutations in XPB, XPD, or XPG have symptoms representing combinations of XP and either TTD or CS, depending on the particular mutations. Finally, patients with XP variant (XP-V) possess mutations in the gene encoding DNA polymerase  $\epsilon$ , which carries out bypass replication past unrepaired CPDs, and have a wide variability in disease severity that does not relate to the mutation type or position.

In the NER pathway, the same set of core protein factors essentially have to be able to recognize an enormous range of different possible abnormalities in the DNA, many of which are remarkably subtle structural changes. It appears that this is achieved by a complex but elegant step-by-step process rather like a “decision tree analysis” that involves the sequential screening of the DNA structure by the multiple XP subunits, each analyzing the DNA for a different abnormal characteristic (Naegeli and Sugawara, 2011).

### Biography

Edward S Tobias

Qualifications: BSc (1st class Hons), MBChB (Commendation), MRCP, PhD (Molecular Biology), FRCP.

Dr Tobias' research group aims to improve the understanding of a variety of medical genetic disorders. The group is closely linked with the West of Scotland Regional Genetics service with several projects arising from the molecular investigation of patients with clinical genetic conditions that range from single gene disorders to complex diseases. The group has strong interests in the genetic basis of long QT syndrome (in collaboration with the FANS network and Generation Scotland) and congenital Mullerian abnormalities, in addition to the role of tumor suppressor genes in human cancer.

Dr Tobias has multiple collaborators within and outside the United Kingdom. Please note that the Publications and Grants pages are currently being updated. Dr Tobias had previously gained an MRC Training Fellowship and won a prestigious GlaxoWellcome/GlaxoSmithKline Senior Clinical Fellowship. He had previously discovered a new cancer gene (submitted to the international Genbank database and leading to papers in *Oncogene* and in *Nature Genetics*). Recent molecular genetic work identifying a new candidate tumor suppressor gene was graded "Excellent/clearly outstanding" by the Scientific Committee of the Chief Scientist Office. In addition, very recent work in elucidating the parent-of-origin effect in SDHD-related tumorigenesis led to the award of a prize to Dr Tobias from the British Society of Human Genetics (September 2011) and to a paper now in press in the *Journal of Clinical Endocrinology and Metabolism*. Two other projects have led to the award of prizes.

# CHAPTER 18

## The Biological Basis of Aging: Implications for Medical Genetics

*Junko Oshima and George M Martin*

Department of Pathology, University of Washington, Seattle, WA, USA

Division of Medical Genetics, Department of Medicine, University of Washington,  
Seattle, WA, USA

This article is a revision of the previous edition article by George M Martin, volume I, pp 443–455, © 2007, Elsevier Ltd.

### 18.1 INTRODUCTION

Evolutionary biology has provided a robust theory to explain why we age, but we have much less confidence that we understand how we age, by which we mean the proximal molecular mechanisms of aging. Medical geneticists are in a good position to advance our knowledge of such mechanisms. The first strategy is the time-honored approach of mapping, cloning, and characterizing the relevant gene actions underlying important late-onset disorders of aging, such as dementias of the Alzheimer type, atherosclerosis, ocular cataracts, type 2 diabetes mellitus, osteoporosis, osteoarthritis, and cancer. Significant progress has been made using this strategy, including major advances in our understanding of segmental progeroid syndromes such as the Werner and Hutchinson–Gilford syndromes. The second strategy is to investigate the genetic basis for unusually well-preserved structure and function during the latter half of the usual life span. Unfortunately, medical geneticists have been too preoccupied with disease and, with some notable exceptions (e.g. studies of centenarians), physicians and geneticists have not shown a strong inclination to investigate exceptional well-preserved late-life phenotypes. The new statistical and molecular tools at our disposal are impressive, but they have not been matched by the application of sensitive functional assays.

### 18.2 WHAT IS AGING?

Some gerontologists, particularly those interested in the aging of plants, sharply differentiate between the terms aging and senescing. Senescent changes, they would

argue, are those structural and functional changes that occur near the end of the life cycle of a cell, tissue, organ, or organism, and are associated with the impending death of the tissue or organism. By contrast, the term aging would be used for any change in structure or function throughout the life cycle. In other words, some would argue that “aging begins at birth.” Most gerontologists who work with mammals and human subjects, however, use the two terms more or less interchangeably. While different scholars define human aging in various ways, most include exponential increases of age-specific mortality rate and declines of the physiological functions as general characteristics of human aging processes. These parameters were primarily derived from cross-sectional population studies. Researchers of basic biology of human aging at the organismal level have a major difficulty that stems from the fact that, unlike model animals, humans are genetically heterogeneous and undergo behavioral and environmental changes throughout their lifetime. Moreover, due to the relatively long life span of humans the cohort studies of longevity, for example, take many years to complete. One approach to testing the validity of the population studies of human longevity and aging is to compare the findings of other model organisms such as yeast (*Saccharomyces cerevisiae*), fruit fly (*Drosophila melanogaster*), worm (*Caenorhabditis elegans*) and mice, with those from *Homo sapiens* (1). They created a large segment of the foundations for the progress we have seen in human biology. Moreover, their contributions have typically been more incisive, in part because of the experimental tractability of their materials.

While none would deny the importance of development in determining the subsequent life history of an organism, most gerontologists are concerned with declines in structure and function that gradually and insidiously unfold after the organism has achieved the young, mature adult phenotype. At the level of populations, these functional declines translate into an exponential increase in the force of mortality over unit time—the hazard function or instantaneous mortality rate (2,3). This is the famous Gompertz relationship (4). This was modified by Makeham (5), who included a constant,  $A$ , to account for kinetic departures presumed to have resulted from causes of death during the early life history that were age-independent. The Gompertz–Makeham equation can thus be given as the sum of two types of mortalities, age-independent and age-dependent, the latter exhibiting exponential kinetics over the adult life span:

$$\mu_x = A + Re^{ax}$$

where  $\mu_x$  is the force of mortality at a given age,  $x$ ;  $A$  is the Makeham constant;  $R$  is the hypothetical value for the force of mortality at birth, the lowest force of mortality, or the  $Y$  intercept in a graphic plot of age ( $X$ -axis) versus force of mortality ( $Y$ -axis) (Figure 18-1);  $e$  is an exponent; and  $\mu$  is a constant representing the slope of the graphical plot (Figure 18-1). Figure 18-1 illustrates differing rates of exponential increases in the force of mortality for two non-inbred wild-type murine species

**FIGURE 18-1** Gompertz function plot of the age-specific mortality rates for combined sexes of two different murine species of contrasting maximum life-span potentials but of comparable size. Both species were wild-type and randomly bred from small cohorts captured near the Argonne National Laboratories (Argonne, IL) by the late George A. Sacher. They were housed under essentially identical conditions (caging, bedding, humidity, temperature, diet) in adjacent animal rooms with no special efforts to establish specific pathogen-free conditions (G. A. Sacher, personal communication to G. M. Martin). The longer lived species (●), *P. leucopus*, was found to have a maximum life span of about 8 years, approximately twice that of *M. musculus* (m). (From Sacher, G.A. *Evolution of Longevity and Survival Characteristics in Mammals*. In *The Genetics of Aging*; Schneider, E.L., Ed.; Plenum Press: New York, 1978.)

despite comparable values for  $R$ . These two species, *Peromyscus leucopus* and *Mus musculus*, are of approximately the same size and were housed and fed throughout their lifetimes under identical conditions (6). The maximum life span of *Peromyscus* sp. was found to be about 8 years, about twice that of *Mus* sp. These data illustrate the importance of genetic factors in the determination of approximate life potential. Given the considerable evolutionary distance between these two species (at least 15 million years), this is not a surprising result. Mortality rates of different human populations in the twentieth century also followed Gompertz–Makeham relationship until they reach to very old age (2,3,7).

Experiments employing very large populations of aging cohorts of fruit flies and medflies have been reported as showing dramatic departures from Gompertz kinetics within the oldest cohorts, with apparent decreases in the force of mortality at very advanced ages (8). Very aged flies, however, may become virtually immobilized and may therefore be protected from environmental hazards related, for example, to attempts at flight. Declines in age-specific mortality rates have also been seen for very aged individuals in human populations (9). Perhaps this observation might also be explained by behavioral changes (e.g. a more protective environment) in extreme old age. It will nevertheless be prudent to explore various non-Gompertzian models of mortality in human populations that adequately describe mortality at extreme ages. The existence and estimate of the upper limit of the human longevity or maximum life span of human has been a focus of debates, although it is generally believed to be around 125 years based on the verified longest lived human (10).

Functional declines can be documented in virtually every organ systems starting shortly after sexual maturation. Most physiologic declines, at least in cross-sectional

**FIGURE 18-2** Linear declines of functional assays for several different human physiological parameters as studied cross-sectionally by the late Nathan W. Shock and colleagues. The values are expressed as percentages of the average performances of healthy 20- to 35-year-old male subjects. (a) Fasting blood glucose. (b) Nerve conduction velocity. (c) Cardiac index (resting). (d) Vital capacity and renal blood flow. (e) Maximum breathing capacity. (f) Maximum work rate and maximum oxygen uptake. (Adapted from Shock, N. W. *Systems Integration*. In *Handbook of the Biology of Aging*; Finch, C. E., Hayflick, L. Eds.; Van Nostrand-Reinhold: New York, 1977.)

studies, exhibit linear declines, the slopes of which are variable (Figure 18-2) (11). Declines in the various physiological processes (and underlying molecular and biochemical processes) that maintain optimum functions are likely to “set the stage” for the plethora of late-life disorders and diseases, some 87 of which have recently been tabulated, all of which are subject to both genetic and environmental modulations (1). However, observations of exponential increases in the force of mortality within populations should not lead one to conclude that underlying processes of aging or incidences of geriatric diseases necessarily exhibit exponential kinetics. Consider, for example, the world records of marathon runners, which select for the most robust, physically fit members of our population. This is an attractive assay, as it tests for fitness of multiple organ systems and one’s ability to maintain metabolic homeostasis. Declines are observable during the fourth decade, later than what is the case for sprinters. This probably occurs, in part, because it takes considerably more training and experience in perfecting one’s optimal pacing for a marathon. It also takes years for the gradual development of such compensatory processes as cardiac muscle hypertrophy. For a remarkably wide range of sports, peak activity occurs during the third decade (12).

Many major diseases of late life, however, show exponential increases in age-specific incidence and prevalence, although there may be slight declines in age-specific incidence at very advanced ages, raising the question of selection for genotypic resistance against specific late-life disorders. Alzheimer disease serves as a good example (13,14). Figure 18-3 summarizes the results of several community-based studies of the age-specific incidence of late-life dementias, most of which are due to dementias of the Alzheimer type (15).

Longitudinal studies of physiologic parameters may exhibit striking variation among individuals (16). Figure 18-4 illustrates the case of a measure of renal function. By this measure, some individuals show no evidence of a decline in renal function; some may have superior compensations for structural alterations (17). Are any of these varied patterns of functional decline (or lack of decline) in apparently normal aging human subjects determined, in part, by constitutional differences in the genotype? Essentially no research has been carried out to address this important question. Medical geneticists have an obvious bias in favor of the discovery of mutations and deleterious allelic variants. There is a great need to define allelic variants that, in ordinary environments, are associated with the maintenance of enhanced structure and function during aging. One such example may be the ApoE2 allele, the prevalence of which is significantly increased in centenarians (18). The APOE2 results are understandable in that there is evidence that carriers are provided with some protection against Alzheimer disease (19).

There is very strong evidence indicating a major role for the constitutional genotype in the susceptibility to various familial and “sporadic” forms of Alzheimer disease. In addition to the apparent protection by the E2

**FIGURE 18-3** Evidence for exponential increases in the age-specific incidence of probable Alzheimer disease in six different community-based studies. (From Breteler, M. M. B. et al. *Epidemiology of Alzheimer Disease*. Epidemiol. Rev., 1992, 14, 59–82.)

allele of ApoE noted above, individuals carrying the E4 allele, particularly homozygotes, are clearly at elevated risk to develop the disease (20). ApoE4 may act as an age-of-onset modifier for the common relatively late-onset forms of the disorder. There may be multiple mechanisms underlying the effects of the e4 allele (21). The lay perception that aging is accompanied by a global loss of cognitive function is certainly incorrect. Only selected regions of the nervous system appear to be particularly susceptible.

The other type of terminally differentiated cell receiving special attention from gerontologists is the multinucleated skeletal muscle cell. Structural and functional declines in skeletal muscle vary from muscle to muscle, with weight-bearing muscles more susceptible; the rates of these declines accelerate after about age 70 (22). At least some proportion of the pathology is likely to be related to denervation atrophy. Disuse atrophy is also an important component, as evidenced by the significant gains in muscle strength in even very aged subjects following a modest conditioning regimen (23). Old skeletal muscle is also more susceptible to contraction-induced injury and is less subject to repair via satellite cell-mediated regeneration (24).

**FIGURE 18-4** Longitudinal studies of creatinine clearance (an approximate measure of the glomerular filtration rate) for a representative sample of a subset of 446 clinically normal male volunteers in the Baltimore Longitudinal Study of Aging of the National Institute on Aging followed between 1958 and 1981. The results could be classified in one of three major patterns. The top panel illustrates substantial rates of decline in this measure of renal function for six representative subjects who were followed for 8–14 years. The middle panel illustrates a pattern of slight, but significant decline for six representative subjects followed for 11–22 years. For the six representative subjects in the bottom panel, who were followed for periods of 15–21 years, there were no apparent declines in this measure of renal function. (From Lindeman, R. D. et al. *Longitudinal Studies on the Rate of Decline in Renal Function with Age*. J. Am. Geriatr. Soc. **1985**, 33, 278–285.)

Many postreplicative aging cell types gradually accumulate a mixture of complex fluorescent pigments called lipofuscins. These are likely to vary in composition from tissue to tissue. Most investigators believe that all lipofuscins are the products of lipid peroxidation reactions. They could therefore be regarded as evidence in support of theories of aging that invoke oxidative alterations of macromolecules. That lipofuscins are markers of some underlying aging process is a theory supported by three lines of evidence. First, they appear to be almost invariable features of aging in an amazing variety of organisms, including certain strains of fungi under certain growth conditions (e.g. *Podospora anserina* and *Neurospora crassa*), paramecia, nematodes, snails, fruit flies, houseflies, frogs, parrots, house mice, rats, guinea pigs, cats, dogs, pigs, monkeys, and humans (25,26). Second, quantitative studies of lipofuscin rates of accumulation in the hearts of dogs and humans indicate appropriate correlations with the life-span potentials of those species (27). (No such correlations have been observed, however, among cardiac tissues from a group of primates of contrasting life spans (28).) Third, age-related increases in concentrations of at least some classes of lipofuscins are blunted by caloric restriction, an intervention known to increase life span in mammals (29,30).

The importance of extracellular aging has been emphasized by the late Robert R Kohn (31). Long-lived proteins, such as lens crystallins and collagens, are particularly susceptible to a variety of posttranslational alterations. Diabetics, who have many progeroid features, are particularly susceptible to glycation of proteins (32). Advanced glycation end products may also play an important role in the genesis of osteoarthritis (33). Modified matrix components could perturb cell–matrix interactions and hence change cell function. Such a scenario has been suggested to play a role in the genesis of atherosclerosis (34). It remains to be seen which of the numerous human mutations involving matrix proteins can inform us as to pathogenetic mechanisms in the normative aging of the extracellular environment.

### 18.3 WHY DO WE AGE?

Evolutionary biologists believe that they have an answer to the ultimate cause of aging in age-structured populations (i.e. populations that consist, at any given time, of cohorts of varying chronological ages) (35). Simply put, we age because senescent phenotypes escape the force of natural selection (36). This theory was developed for the

case of species with age-structured populations, a situation that occurs when there are serial episodes of reproduction in an individual's lifetime, as opposed to one massive “big-bang” production of progeny in short-lived animals (37). For human populations, the late William Hamilton showed that the force of natural selection for or against alleles that do not reach phenotypic expression until about the age around 45 years is essentially nil (38,39). More recently, a mathematically rigorous challenge to Hamilton's theory has been published (40). It describes a scenario whereby the force of natural selection can actually increase during aging. There are in fact some species of fish that continue to grow and, as such, become more like predators than prey. Under those circumstances, it is easy to imagine declines in the force of natural selection with age.

August Weissmann, one of the giants of nineteenth century biology, postulated a limited life span of somatic cells, from which he proposed programmed death theory with the idea that aging is good for the species in that it results in enhanced resources for the young. While a finite replicative capacity of somatic cells was later confirmed experimentally (41), there has been no good evidence that aging evolved because it was adaptive for the species or the individual. Essentially all population geneticists who have considered this issue have concluded that aging is nonadaptive. A striking demonstration that single gene mutations can extend the life span of nematodes, fruit flies and mice—sometimes dramatically (42)—provides evidence against the classical evolutionary biologic theory of aging, which would predict a highly polygenic modulation. Moreover, we have known for many decades that a single environmental manipulation, caloric restriction (or, more conservatively, dietary restriction), can substantially enhance life span in a remarkably wide range of species (reviewed by Masoro (43)). Some would argue that these observations support a “programmed” mechanisms of aging—that is something more in the line of sequential, determinative changes in gene expression that actively produce aging. One interpretation of both the single gene mutation and caloric restriction experiments is that all or many of them are examples of *diapauses*—time-outs from the business of reproduction during “bad times”—be they nutritional, climatic, or other environmental challenges.

In terms of genetic mechanisms that form the basis of the classical evolutionary theory of aging, two ideas currently dominate the field. The first, championed by the late Peter Medawar, is generally referred to as “mutation accumulation” (44). This is an unfortunate name, as the mutations in question are not somatic mutations developing during the life span, but germ line mutations that do not reach phenotypic expression until late in the life course, when the force of natural selection would be attenuated. Huntington disease is the prototypical example. Haldane was puzzled by the surprisingly

high prevalence of this disorder, which exceeds 15 per 100,000 in some western European populations (45), while germ line mutations typically have frequencies of about one in a million. Haldane suggested that the reason the mutation survived in the population was because of its delayed manifestations, thus escaping the force of natural selection (46). If that were the case, there would be selection for “suppressor alleles” that progressively delayed the age of phenotypic expression. Medawar concluded that many such suppressors might only delay these deleterious effects (44); eventually, however, the delayed age of expression would be such that there could be little or no influence of natural selection. This scenario, especially when coupled with the other mechanisms discussed below, would result in an enormous degree of heterogeneity in patterns of aging among individuals in out-breeding populations. Thus, each of us may be essentially unique in precisely how we age.

The second dominant idea was first clearly enunciated by George C Williams (47), and has been referred to as antagonistic pleiotropy; it has been elaborated by Michael R Rose (36). By this view, some varieties of genes might have been selected because of good effects early in the life span, but may also have deleterious effects late in the life span, thus contributing to aging phenotypes. As one potential example, Williams speculated that alleles selected because of enhanced incorporation of calcium into bones might be responsible for forms of calcific arteriosclerosis, when acting over long periods. There have been many suggested examples in the literature, but they have been hard to definitively establish. Potential examples include atherosclerosis (48), the role of the apolipoprotein E4 allele in Alzheimer disease (49), common late-life cancers (50), and immunosenescence (51). Medical geneticists are in a good position to suggest a number of other examples, and perhaps to provide compelling supportive evidence. Such research has the potential to illuminate the most basic aspects of the aging problem.

Another conceptual formulation, one that overlaps with what has been discussed above, is that there is, inevitably, a trade-off of energetic resources expended by an organism for purposes of reproduction and resources devoted to the maintenance of the macromolecular integrity of the organism. Examples include repair of DNA, scavenging of abnormal proteins, and replacement of effete somatic cells; this is the disposable soma theory of Tom Kirkwood (52). These ideas can be generalized as life history “optimization” theories of aging (53). Experimental evidence in *Drosophila* sp. supports both optimization theories and the mutation accumulation theory of aging (53,54). The relative quantitative contributions of each theory, however, particularly in *H. sapiens*, are completely unknown. As pointed out by Partridge and Barton (53), the resolution of this issue has potentially profound implications for the future life history of our species. If optimization mechanisms predominate, any life-span extensions may be offset by the trade-off

of lower early fertility, delayed maturation, and potential increases in early life history morbidity and mortality. If mutation accumulation mechanisms prevail, enhanced life span attributable to the elimination of such constitutional mutations would presumably have few effects on early life-span structure and function. Given a major role for optimization theories, a continuation of the present secular trends of elective delays in the ages of reproduction in the developed societies would predict the emergence, by indirect selection, of increased life spans and related declines in early fertility after several centuries of continued evolution of our species. However, it has been well documented that advanced parental age is associated with increases in germ line mutations. Of particular relevance to our interest in late-life disorders is the evidence that there is a large paternal age effect for point mutations (55). Such secular trends could therefore be associated with increases in germ line mutations, with potential deleterious effects in subsequent generations. It has been difficult, however, to confirm a relationship of paternal age and the occurrence of nonfamilial varieties of such common polygenic late-life disorders such as Alzheimer disease or prostate cancer (56).

At a more fundamental level, one can ask why one observes such striking variations in the life spans of various mammalian species. While such variation is obviously related to the constitutional genotype, it does not necessarily follow that aging is “programmed”—at least in the sense of concerted, determinative, sequential gene action comparable to what one observes in development. The most satisfying idea invokes differential impacts of environmental hazards (e.g. accidents, predation, drought, starvation, infectious diseases) during the emergence and maintenance of various species. This is nicely articulated in a popular book on aging (57). Species with comparatively high hazard functions would be expected to evolve life history strategies that emphasize rapid maturation, high fecundity, early fecundity, and short life spans. An attenuation of those hazards could set the stage for the emergence of sibling species with a more leisurely rate of maturation, lower early fecundity and longer life spans. One of the few field biology studies to examine this idea has in fact provided strong support for that hypothesis (58). Contrary findings have been reported, however, for different species in different ecologies (59).

The evolutionary formulations of the nature of aging have a number of interesting and important implications, in addition to those noted above. Let us summarize some of these propositions:

1. Stochastic processes: These are likely to play a major role in senescence. This follows from the conclusion that one is not dealing with a determinative sequence of concerted gene action but rather with an epiphenomenon of selection for gene action designed for reproductive fitness. Consider the analogy with a spacecraft engineered to function for a given period of time in order to complete a specific mission. Engineering

specifications for indefinite maintenance of the craft would be prohibitively expensive or impossible. One would therefore anticipate an element of chance as to which components will initially exhibit structural and functional failures and when such failures will be detectable with the available diagnostic facilities. Many major geriatric diseases of humans (e.g. cancer, strokes, coronary thrombosis) are surely based on stochastic events. In the case of malignant neoplasms, selection for a series of random somatic mutations is the key to the understanding of the pathogenesis. Overall longevity also is subject, in part, to stochastic laws. There are numerous examples in which investigators have rigorously controlled both environment and genotype, yet have observed marked variations in longevity. The most convincing example comes from studies of *C. elegans*, which can be grown in chemically defined medium in suspension cultures, thus ensuring rigorous control of the environment (60).

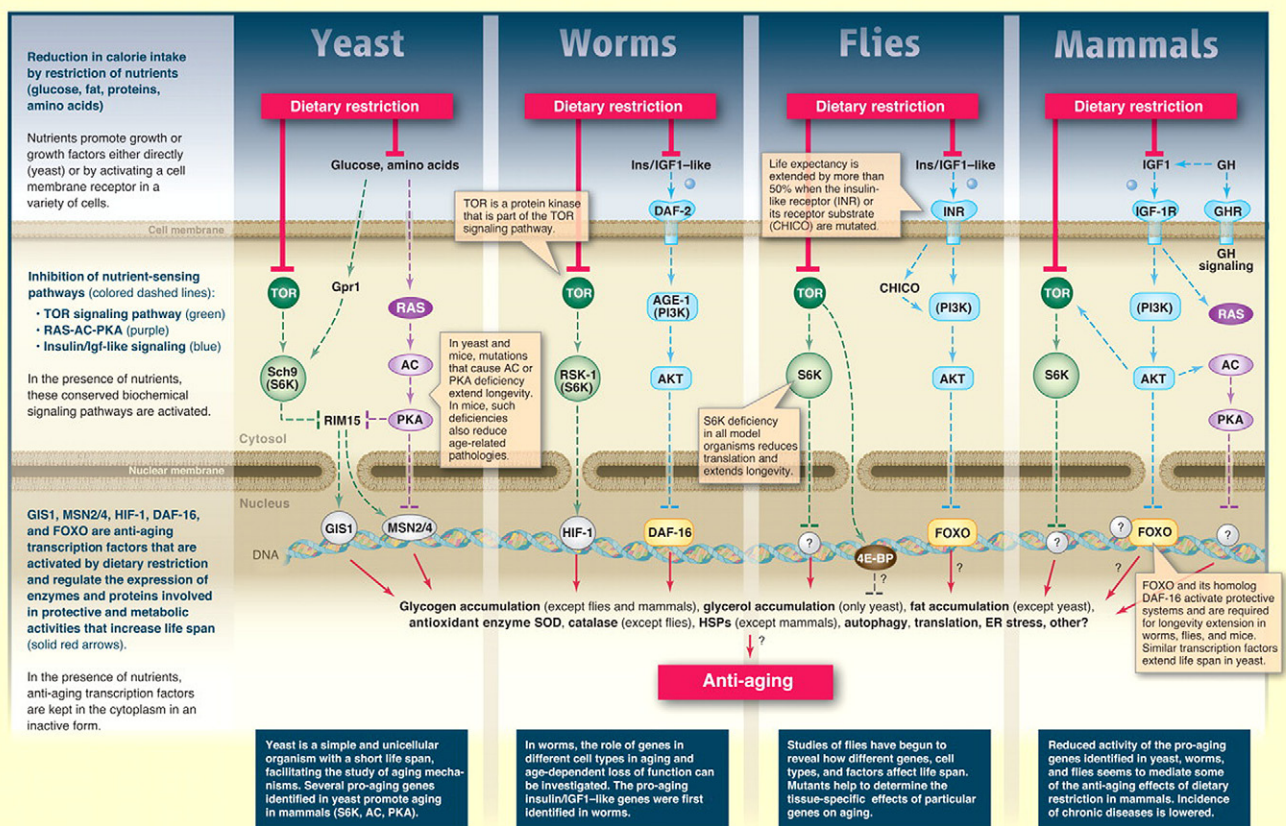

2. Polygenic basis: There is a polygenic basis for aging. There is no reason to believe that the optimization theories or mutation accumulation theories involve only a few genes. Indeed, for the case of the successful experiments involving indirect selection for increased life spans in genetically heterogeneous wild-type stocks of *D. melanogaster*, genetic analysis indicated genes on all of the major chromosomes (61). Martin (62) estimated (as an upper limit) that allelic variation or mutation at close to 7% of loci of the human genome has the potential to modulate varying aspects of the senescent phenotype. A different and more conservative estimate—the number of genes likely to have evolved in the hominoid lineage leading to humans (and thus could be associated with the increased life span of *H. sapiens*)—gave a figure of 0.6% of functional genes (63). Neither estimate can be characterized as oligogenic.
3. Multiple mechanisms: There are likely to be multiple mechanisms of aging, although there would be selective pressure toward some degree of synchronization of the ages of expression of phenotypic effects resulting from independent mechanisms. This proposition follows from the randomness of the accumulated constitutional mutations and from the great variety of types of gene action that could be involved in “trade-off” types of gene action. Against this proposition, however, is the fact that a single environmental manipulation—caloric restriction—regularly leads to life-span extension in rodents, or at least those that have been selected for the easy life of the laboratory setting (reviewed by Masoro (43)). We have little information on the effects of caloric restriction in the wild, however. The life course histories of organisms, whose evolutionary history reflected exceptionally high environmental hazard functions, such as the mice and rats used for most of the calorie-restriction experiments, are quite distinct from those of the higher primates (57). It is therefore not at all clear that caloric restriction would

make a significant impact on the life-span potentials of human subjects. Evidence is pointing toward the conclusion that caloric restriction may delay the onset of age-associated pathologies and reduce the incidence of common age-related disorders and age-related deaths (64). We shall have to await the final outcome of current research in rhesus and squirrel monkeys (reviewed by Roth et al. (65)) to know how likely such an effect will obtain for our species. Meanwhile, common sense tells us that we should avoid gluttony!

4. Species specificity: There is likely to be a degree of species specificity in relevant gene actions. We have already developed certain of these arguments, but let us consider an extended argument. If aging is in fact an epiphenomenon—a by-product of selection for alleles ensuring an optimal degree of reproductive fitness in a given environment—there is no a priori reason to expect identical scenarios of gene action among very different species. Consider the striking differences in the behavioral patterns among different species that lead to

successful matings. There are surely a wide variety of different loci involved, and those that are operative in fruit flies must surely differ from those that are relevant for man! Nevertheless, it is quite possible that there are a number of common mechanisms among groups of related species (including all mammals), and it is even conceivable that such global mechanisms as oxidative damage to macromolecules underlay the aging of all or most organisms (see, e.g. the previous discussion on lipofuscins). This is the rationale for carrying out comparative gerontologic research. Recent research in that direction has in fact revealed evidence for at least one “public” mechanism of aging (54). Remarkably, “leaky” mutations in comparable neuroendocrine signal transduction pathways involving insulin-like growth factor (IGF) receptors and the nuclear translocation of a transcription factor can lead to substantial extensions of life spans of such diverse organisms as *C. elegans*, *D. melanogaster* and *M. musculus domesticus* (Figure 18-5) (42). At first blush, these observations

## Conserved Nutrient Signaling Pathways Regulating Longevity

**FIGURE 18-5** Evidence for a partially conserved “public” mechanism for the modulation of aging in yeast, worms, fruit flies, laboratory mice, and, possibly humans. These signal transduction pathways evolved to modulate metabolism under transient adverse environmental conditions, during which gene actions that enhance the protection of somatic cells are up-regulated while further growth, development, or reproduction is postponed. Certain mutations in these pathways were found to substantially enhance the life spans of laboratory strains of model organisms amenable to genetic analysis. Mutations so far studied in this general pathway in humans result in pathology. The possible effects of a wider spectrum of such mutations upon the longevity of humans are not yet understood. (From Fontana, L.; Partridge, L.; Longo, V.D. *Extending Healthy Life Span from Yeast to Humans*. Science 2010, 328, 321–326.)

would appear to contradict the conclusion, discussed above, that aging is under polygenic controls and that multiple mechanisms are at work. The authors' interpretation of these important discoveries, however, is that they are examples of diapause—nature's “time-outs” from the business of reproduction when faced with conditions of nutritional, climatic, or other environmental challenges (1). These can best be considered as “reprieves”; they will be eventually trumped by other gene actions that, unlike diapause, have escaped the force of natural selection.

5. Intraspecific variations: There are likely to be significant intraspecific variations in phenotypic patterns of aging, particularly in humans. This also follows from many of the arguments discussed above. Given the polygenic nature of aging, the likelihood of a variety of mechanisms, a strong stochastic component, the realization that one is dealing with alterations in all body systems, and the enormous genetic and environmental heterogeneity in our species, one would certainly predict substantial differences in the way it plays out in individual subjects. Every clinician has witnessed this phenomenon first-hand. While differential impacts of the environment are likely to be partially responsible for such variations, the challenge for medical geneticists is to dissect out specific major and minor genetic factors responsible for particularly favorable or unfavorable nature–nurture interactions.
6. Plasticity: The life span of a species should exhibit a degree of plasticity. This follows directly from the arguments on the nature of gene action in aging discussed above and from the experimental results in *Drosophila* sp. Nonetheless, there are likely to be some severe constraints on such plasticity—constraints related to the basic architecture of the organism. We do not expect a fruit fly to live as long as a mouse, without essentially creating a new species.

## 18.4 HOW DO WE AGE?

We now turn to a more systematic consideration of the present state of our knowledge concerning the underlying molecular mechanisms of aging. In contrast to the reasonably satisfying evolutionary explanations for why we age, there is no consensus as to how we age, although the research programs of a growing number of investigators appear to be motivated by the theory that oxidative damage to macromolecules, including those mediated by chemical-free radicals (the “free radical theory of aging”) (reviewed by Muller et al. (66)), are of paramount importance.

### 18.4.1 Alterations in Proteins

In 1963, Orgel introduced the protein synthesis error catastrophe theory of aging (67,68). It was proposed

that transcriptional and/or translational errors in the synthesis of proteins that were themselves used for the synthesis of proteins (e.g. DNA-dependent RNA polymerases, ribosomal proteins) could result in an exponential cascade of errors involving essentially all proteins, leading to cell and organismal death. Biosynthetic errors in protein synthesis appear to be rare, however, even in old organisms (69). Although most gerontologists have abandoned this theory, very few tests of the theory have been carried out with postreplicative cells in vivo (70). By contrast, there is a growing body of evidence indicating the prevalence of posttranslational modifications in proteins in aging tissues; although, of the more than 140 major and minor known modifications of proteins, only a few have been studied in aging cells, tissues and organisms (71). Beginning with a classic paper on senescent nematodes by Gershon and Gershon (72), many studies have demonstrated an accumulation of immunologically detectable, but enzymatically inactive, enzyme molecules in various mammalian tissues. These may result from a variety of posttranslational modifications, including subtle conformational changes (69). There is currently a great deal of interest in oxidative alterations (73). Metal-catalyzed oxidation systems have the potential to inactivate enzymes oxidatively via attacks on the side chains of certain amino acids, with the formation of carbonyl derivatives. The side chains of histidine, arginine, lysine, and proline are particularly susceptible. The sulfhydryl groups of methionine are also susceptible to oxidation. Other posttranslational changes that can be observed in aging cells include racemization, deamidation, isomerization, phosphorylation, and glycation.

Many gerontologists believe that glycation, the spontaneous nonenzymatic reaction of glucose with proteins and nucleic acids, may be a major factor in the development of certain age decrements, as well as complications of diabetes mellitus. Glycation is the slow, spontaneous reaction of the aldehydic form of glucose with free amino groups to form a Schiff base, which subsequently rearranges to form a stable Amadori product. Subsequent reactions, possibly involving oxygen radicals, generate more complex products referred to as advanced glycosylation end (AGE) products. Some of these compounds, including pentosidine, have been characterized. Antibodies to the AGE products have been generated and used to map their distribution to neuritic plaques and tangles and to other sites (32). Because the levels of AGE products increase with age and with elevated blood glucose, cross-link proteins, and change their physical and biologic properties, they are thought to underlie the development of atherosclerosis, cataracts, and peripheral neuropathies. In addition, macrophage receptors bind to the AGE products and initiate the secretion of inflammatory cytokines such as the tumor necrosis factor (74). Thus, glycation represents a progressive age change linked to age-associated disabilities. Support for these ideas has come from experiments in aging dogs, in

which it was possible to reverse myocardial stiffness and improve cardiac function by the administration of an experimental compound known to break the cross-links associated with the formation of advanced glycation end products (75).

Calorically restricted rodents, which have substantially increased life spans, exhibit evidence of both enhanced defenses against reactive oxygen species and reduced levels of protein glycation (associated with decreased levels of plasma glucose). Such results suggest that both the free radical theory of aging and the glycation theory of aging may be operative and potentially synergistic (76). A number of different types of amyloids accumulate in mammalian tissues during aging (77). In their advanced states, they are detected extracellularly as protein aggregates associated with proteoglycans and other proteins. Each type is derived from a different precursor protein. These include the beta-amyloid protein of Alzheimer disease and the aging brain a transthyretin-derived amyloid in peripheral nerve tissues, autonomic nervous system, choroid plexus, cardiovascular system, and kidneys; atrial amyloid derived from the atrial natriuretic peptide the amylin-derived amyloid in the pancreatic islets of Langerhans (78); systemic amyloid AA derived from apolipoprotein A-II (79); and possibly unique types of amyloid in the anterior pituitary gland, intervertebral discs, the aortic intima and media, aortic heart valves and the adrenal cortex. In certain of these conditions, mutations or polymorphic variants in the precursor protein greatly accelerate the rates of deposition of the derivative amyloids.

It is a challenge for the future to discover common denominators underlying this remarkable propensity of mammalian tissues to accumulate these different types of abnormal proteins. Obvious approaches would include more detailed studies of alterations in protein turnover with age (including the turnover of amyloid deposits) and how such turnover might be modulated by endocrine and neuroendocrine factors. Another promising and relatively new area of research seeks to define gene products that function in the repair of altered proteins. An example is the catalysis of the transfer of a methyl group from *S*-adenosylmethionine to L-aspartyl and D-aspartyl residues by protein carboxyl methyltransferases (ED 2.1.1.77). These enzymes have the potential to repair abnormal proteins via the conversion of L-isoaspartyl residues to L-aspartyl residues (80). This enzyme is polymorphic in humans, raising the question of the differential repair of such classes of altered proteins during aging in human populations (81).

## 18.4.2 Alterations in DNA

**18.4.2.1 Nuclear DNA—Epigenetic Events.** Given the fact that, for most genetic loci, only two alleles are present, nuclear DNA would appear to be a particularly vulnerable target for damage during aging. Historically,

the first specific type of somatic “mutational” theories of aging was proposed by a physicist, Leo Szilard (82). He envisioned random “hits” that would inactivate entire chromosomes or chromosome arms. In modern terms, such inactivations could conceivably be associated with epigenetic events, as for the case of the random inactivation of one of the two X chromosomes of the human female during embryonic development and the processes of parental genomic imprinting. There is no good evidence of widespread heterochromatizations or inactivation of large chromatin domains during aging. In fact, at least for the case of mice, there is evidence of a reactivation of certain gene loci on a previously inactive X chromosome during aging (83–85). No such reactivation could be demonstrated for the case of the *HPRT* locus of heterozygous human females (86). Reactivation has also been demonstrated for a genomically imprinted autosomal locus in mice (83). Global losses of 5-methyl cytosine have been demonstrated in aging fibroblast cultures (87) and in tissues of two species of aging rodents (88), but there have been few studies of altered methylation in specific domains of specific genes during aging. In one such study, hypermethylation was mapped to the proximal 5′ spacer domain of ribosomal DNA genes of aging mice; silver stains of cytogenetic preparations revealed that the ribosomal gene cluster on chromosome 16 was preferentially inactivated (89). It remains to be seen, however, whether this remarkable result reflects some developmental, adaptive process in laboratory mice or in the particular strain of mice investigated, as the biochemical changes were observed as early as 6 months. A form of gene-specific methylation of CpG islands has clearly been established to progress steadily into old age in human subjects. It is associated with the silencing of the estrogen receptor gene of a subset of cells of the colonic mucosa (90). A striking finding in that study was that, of a set of 45 colorectal human tumors examined, including those in very early stages of oncogenesis, estrogen receptor expression was either diminished or absent. Moreover, the introduction and expression of an estrogen receptor gene in a line of colon carcinoma cells resulted in marked growth suppression. This important paper therefore demonstrates a link between a presumably epigenetically based progressive repression of a specific gene during aging and the susceptibility to the development of a common type of cancer of aging.

Using the yeast model of replicative aging, Lenny Guarente and his colleagues highlighted a key role of NAD-dependent histone deacetylation in the regulation of energy metabolism, genomic silencing and aging (reviewed by Imai and Guarente (91)). There is a great deal of current research in various organisms on homologs (sirtuins) of the yeast Sir2 gene responsible for the histone deacetylation (91,92). A variety of other changes in gene expression occur throughout the life span, but it remains to be seen which of these alterations are of

primary significance to one or more aging processes and which are merely epiphenomena. One such approach is to explore the effects of caloric restriction (93). A marked transcriptional stress response, with lowered expression of metabolic and biosynthetic genes, is found in aging mouse tissues. These alterations are ameliorated in calorically restricted mice.

**18.4.2.2 Nuclear DNA—Mutational Events.** In 1961, a now classic paper appeared, casting doubt on the validity of somatic mutational theories of aging (94). Taking advantage of the occurrence of a species of wasp in nature—the males of which exist as either haploid or diploid organisms—it was found that there was no difference in the life spans of these organisms. As expected, however, the haploid wasps were much more susceptible to the effects of ionizing radiation. These results were strong evidence against a role for recessive mutations in insects. They did not rule out, however, some role for a combination of dominant and recessive mutations in the aging of such organisms. Moreover, the interpretations are complicated by the occurrence of polyploidy cell types. Finally, those experiments told nothing about the role of somatic mutations of replicating populations of cells in the limitation of life span, since wasps and other insects, with the exception of gonadal tissues and, in *Drosophila*, certain intestinal cells, consist of postreplicative cells. For the case of such replicating populations of cells, there is now compelling evidence that somatic mutations constitute a link between the biology of aging and the biology of cancer. Thus, while much more data are required, there are reasonable correlations of species-specific life spans and rates of development of various neoplasms (e.g. (95)). Clearly, among those genes that evolved in association with the relatively long life spans of *H. sapiens* (the longest lived of all mammalian species), there must be loci conferring enhanced genomic stability in comparison, for example, with those of *M. musculus domesticus*. Moreover, there may be considerable species differences in the patterns of somatic mutation. For mice, for example, there is evidence of a marked susceptibility to cytologically detectible chromosomal mutations during aging (96), while in comparable cell types (renal tubular epithelial cells), there is little evidence for the accumulation of mutations (presumably intragenic) at the *HPRT* locus, a target chosen because of the lack of evidence for selection against such mutations in renal tissue (97). Mutations have been shown to accumulate at the *HPRT* locus of T lymphocytes and in the renal tubular epithelial cells of aging human subjects, however, with higher frequencies of mutation being observed in the epithelial cell type (98,99). The lymphocyte study showed that deletions were relatively common (100). Such accumulations could be attributable to chronology rather than to intrinsic biologic aging. We will require additional research in mammals of contrasting life-span potentials to address this question; an approach

using comparable transgenic reporter constructs may be promising, if these could be comparably buffered from position effects (101).

**18.4.2.3 Nuclear DNA—Molecular Misreading.** What originally appeared to be the accumulation of frameshift mutations in DNA in aging mammals now appears to be the result of transcriptional errors at particularly vulnerable sites, especially those with runs of GAGAG. van Leeuwen has named this phenomenon “molecular misreading.” The process can impact upon the fidelity of transcription of such important loci as the beta-amyloid precursor protein and ubiquitin B (102).

**18.4.2.4 Telomeric DNA.** Perhaps the most robust age changes noted in the nuclear genome of normal somatic cells are alterations in telomere length, leading to replicative senescence (reviewed by de Lange (103)). Telomeres have a highly repetitive structure (TTAGGG in humans and mice) that extends for many thousand of nucleotides at the ends of chromosomes. The telomeres stabilize chromosomal structure and their loss leads to various cytologic aberrations and the arrest of cell division. Current concepts suppose that telomeres in cells of the germ line and in many neoplastic cells are added to the ends of chromosomes *de novo* by a unique enzyme referred to as telomerase, which uses an associated RNA to code for the hexanucleotide repeats. It appears that telomerase is lost or its concentration greatly diminished in the progeny of somatic stem cells (but not in cells of the germ line). Somatic cell telomeres are then duplicated during cell division by DNA polymerases without the assistance of telomerase. It is characteristic of DNA polymerases that they fail to copy some 50–200 terminal bases of the trailing strand and the telomeres are shortened by this amount with every cell division. The shortening of telomeres is strikingly apparent when one examines the telomeric/subtelomeric DNA isolated by appropriate restriction enzyme cleavage from normal human fibroblasts that have undergone large numbers of cell divisions in culture. Exit from the cell cycle may occur as when only a few chromosome arms reach a critical level of shortening, thus activating cell cycle checkpoints (104).

The development of a PCR-based method for the assay of telomere lengths has led to a remarkable association of short telomeres in DNA from peripheral blood of elderly human subjects with mortality; the results were largely attributable to earlier deaths from cardiovascular and infectious diseases (105). Shorter telomere lengths have also been reported in mothers of chronically ill children; the authors surmised that life stress could shorten life span (106). An alternative interpretation, however, is that the mothers of many chronically ill children are more frequently exposed to infectious agents, thus driving proliferation of lymphocytes, resulting in shorter telomeres.

**18.4.2.5 Mitochondrial DNA.** Considerable attention is now being directed to changes in mitochondrial DNA (mtDNA) that might underlie age deficits in metabolism in various mammalian tissues, especially skeletal muscle myocardium and brain (reviewed by Wallace et al. (107)). This is based in part on a growing number of observations that various types of mtDNA mutations accumulate, to varying degrees, in multiple tissues of aging human subjects and in the tissues of other aging mammals. Most of the assays were for large deletions, but tandem duplications and point mutations have also been reported.

mtDNA is closed circular DNA of some 16,569 nucleotides that codes for some of the mitochondrial proteins plus the tRNAs and rRNAs used for mitochondrial protein synthesis. Other components of the mitochondria are coded for by nuclear genes and are transported to the mitochondria. Essentially, all mtDNA molecules are maternal in origin; thus, mtDNA genetic diseases are maternally transmitted.

Based on the frequency and consistent location of common specific age-related deletions, one can postulate that the sequences between the direct repeats are looped out following damage to the DNA by a slip replication mechanism. The damage to mtDNA molecules may be initiated by oxygen radicals generated as a by-product of the oxidative phosphorylation reactions carried out by the mitochondria. The proximity of mtDNA to the sources of oxygen radicals, plus the lack of associated histones, would make mtDNA more vulnerable than nuclear DNA. While certain forms of DNA repair are lacking in mitochondria, other lesions appear to be repaired (108). Thus, the age changes observed could be due to increased damage and/or reduced repair. One important mechanism for repair is the proofreading domain of DNA polymerase gamma, the enzyme that replicates mtDNA. Support for the importance of this function has come from the synthesis of mice with knock-in mutations in that domain; these transgenic mice exhibited progeroid features (109).

In spite of the fact that there are substantial increases in mtDNA damage with age, only a small proportion of the total mtDNA molecules are affected. Indeed, no clear consensus exists as to whether oxidative phosphorylation declines with age. Thus, some investigators doubt that the alterations occurring in mtDNA are a significant factor underlying aging and/or age-associated diseases. Alternatively, it has been proposed that damaged mtDNA molecules preferentially replicate as a local adaptive response to energetic deficits created by impaired mitochondria. An alternative hypothesis is that damaged mtDNA molecules accumulate because they generate fewer altered proteins and are thus less likely to be targeted for turnover; this theory has been referred to as the “survival of the slowest” (110). Thus, as in the genetic mtDNA diseases, it is proposed that the altered DNA molecules are concentrated by a focal expansion

in individual cells, nerves, and muscle fibers, and lead to the death of such cells, perhaps through apoptosis. An increase in mtDNA damage may therefore cause the progressive depletion of single cells without causing major alterations in the remaining cells in the tissue, which would be affected individually and later. Clearly, such a mechanism could play an important role in the decline of CNS function in the development of frailty, impaired wound healing, and other age-associated declines by depleting cells from these tissues.

**18.4.2.6 Germ Line Mutations.** Medical geneticists are well aware of the increased risk to the conceptus of chromosomal types of mutations (mainly aneuploidies) as functions of maternal age. This is, of course, the basis for the clinical practice of counseling women of the availability of prenatal diagnosis. The relationship of paternal age to the increased risk of certain types of mutations has also been well documented (111) and has been mentioned above in a different context. Suffice it to say that, from the point of view of the pathobiology of aging, we remain ignorant of the underlying mechanisms. These important subjects have in fact received substantially less attention by the gerontologic community than the question of somatic mutation and aging.

### 18.4.3 Alterations in Lipids

Given the seminal importance of membranes in cell biology, alterations in the structure of membrane lipids could constitute a primary mechanism of age-related cellular dysfunction and cell death. Most research in this field has addressed the issue of lipid peroxidation, an integral component of the free radical theory of aging. Aspects of this idea have been discussed above, including the ubiquitous nature of lipofuscin pigments as a biologic marker of aging. A second line of research in this field has emphasized age-related increases, in various cell types, of the cholesterol-to-phospholipid ratios of plasma cell membranes, with a consequent decrease in membrane fluidity. However, at least in some cell types, such as neurons of the dorsal root ganglia, the decline in membrane fluidity, as measured by lateral diffusion coefficients, is related to development rather than to post-maturational aging (112).

## 18.5 PROGEROID SYNDROMES OF HUMANS

Having reviewed the present state of our knowledge of the biology and pathobiology of aging, we can now consider spontaneous mutations in man that may modulate the aging phenotype. As we have seen, however, evolutionary theory would argue that no single mutation or polymorphism is likely to modulate all aspects of the senescent phenotype. In a systematic survey of several editions of McKusick's catalog of the Mendelian

inheritance of humans, one of us (GMM) indeed concluded that no single mutation has yet been identified that could be characterized as a global progeria (62). A number of mutations, however, could be characterized as “segmental progeroid mutations,” in that multiple segments of the complex senescent phenotype of man appear to have been affected, whereas unimodal syndromes predominantly impact a single organ (e.g. dementias of the Alzheimer type) (62,113). The responsible mutations include those that impact genomic stability, nuclear structure, numbers of triplet-repeats, and alterations in lipid and carbohydrate metabolism. Some chromosomal aneuploidies (e.g. trisomy 21) also exhibit segmental progeroid features (62). Two best-known examples of segmental progeroid syndromes are Werner syndrome (WS) and Hutchinson–Gilford progeria syndrome (HGPS), which are discussed in more detail in the following.

### 18.5.1 Werner Syndrome

The clinical phenotype of WS (OMIM# 277700) has been succinctly summarized as a “caricature of aging” (Figure 18-6) (114,115). WS patients usually develop normally until they reach the second decade of life. The first clinical sign is a lack of the pubertal growth spurt during the teen years. In their 20s and 30s, patients begin to exhibit a general appearance of accelerated aging with skin atrophy, loss of subcutaneous fat, and loss and graying of hair. They also develop common age-related disorders including type 2 diabetes mellitus, bilateral ocular cataracts (requiring surgery at a median age of 30), osteoporosis; gonadal atrophy (with early loss of fertility), premature and severe forms of arteriosclerosis (including atherosclerosis, arteriolosclerosis and medial calcinosis); and peripheral neuropathy. Multiple cancers can be observed by middle age (116). Our recent survey of WS patients with a molecularly confirmed

diagnosis revealed that the prevalence of cataracts was 100% (87/87) (117). The prevalence of osteoporosis was 91%, hypogonadism 80%, diabetes mellitus 71%, and atherosclerosis 40% at the time of diagnosis. Median age of death in the most recent study was 54 years, a significant increase over what had been observed several decades ago (114,115), perhaps the result of improved medical management. The most common causes of death are myocardial infarction and cancers (117).

Although many clinical features of WS are similar to those observed during “normal” aging, there are significant distinctions. There are a disproportionate number of sarcomas in WS patients: the ratio of mesenchymal cancers to epithelial cancers in WS is approximately 1:1 as compared to 1:10 in general population (116). Alzheimer-type dementia is not common in WS (118). The long bones of the limbs, especially of the lower limbs, are particularly vulnerable to osteoporosis, whereas in ordinary aging the vertebral column is particularly vulnerable, especially in females (119). There is also a peculiar osteosclerosis of the distal phalanges that is not seen during ordinary aging (120). Necrotic skin ulcers and necrosis around ankles and occasionally around elbows, which eventually may require amputation, are characteristic to WS, but rarely seen during normal aging.

Classical WS is caused by mutations of the *WRN* gene on chromosome 8. The locus spans approximately 250 kb and consists of 35 exons, 34 of which are protein coding (121). *WRN* encodes a 180 kDa multifunctional nuclear protein that belongs to the RecQ family of helicases (122). A structural study revealed a unique interaction between the RecQC-terminal domain of *WRN* protein and the DNA substrates during base separation (123). In contrast to other members of the RecQ family, *WRN* protein includes an N-terminal domain that codes for exonuclease activity (124). A single strand-DNA annealing activity in the C-terminal region has also been reported (125). Its preferred substrates resemble various

**FIGURE 18-6** Werner syndrome patients with homozygous *WRN* mutations. (From Hisama, F.M.; Bohr, V.A.; Oshima, J. *WRN's Tenth Anniversary*. Sci Aging Knowledge Environ. 2006, 28, pe18.)

DNA metabolic intermediates, substrates for which its helicase and exonuclease activities function in a coordinated manner, suggestive of roles in DNA repair, recombination and replication (126). The WRN protein is also involved in telomere maintenance (127), which explains the accelerated telomere shortening of fibroblasts derived from WS patients (128). Interestingly, epigenetic inactivation of WRN was observed in sporadic cancers found in general population, supporting a role of WRN as a tumor suppressor by providing genomic stability (129).

To date, more than 70 different WRN mutations have been reported, some of which appear to be specific to certain ethnic groups (130). The majority of these disease mutations result in the truncation of the nuclear localization signal at the C-terminus of the WRN protein (131), which makes mutant WRN proteins unable to enter the nuclei. This seems to be a satisfactory explanation of why we do not observe noticeable phenotypic differences among various common WRN mutations (117,130). WS cases are most frequently reported in Japan, where the prevalence of heterozygotic carriers, as estimated from the most common Japanese mutation, was approximately 1/167 (132). Another region with high incidence of WS is Sardinia, where the prevalence of heterozygous carriers was estimated to be of the order of 1/120 (133). Frequencies of WRN mutations in other population are unknown, as WS may often escape diagnosis.

Some evolutionary biologists would argue that the WS is a poor model of aging, in that it is clear that it would not fit the definition of a set of phenotypes that have escaped the force of natural selection (36).

### 18.5.2 Hutchinson–Gilford Progeria Syndrome

HGPS (OMIM# 176670) is a childhood-onset progeria (Figure 18-7). It was first described by Jonathan

Hutchinson (134) in a boy with baldness and atrophic skin. Hastings Gilford (135) then described a patient with accelerated aging and ateleiosis who died with symptoms of angina pectoris at age 18. HGPS patients are typically normal at birth, but exhibit growth retardation within the first 3–6 months of life along with accelerated degenerative changes of the cutaneous, musculoskeletal and cardiovascular systems (136,137). Baldness and a characteristic “plucked bird appearance” generally develop by age 2. Median age of death in HGPS patients is 13.5 years, and virtually all the patient succumb to myocardial infarction or congestive cardiac failure (138). This is in contrast to patients with the adult-onset progeroid syndrome, WS, whose onset is after puberty (114,136). Unlike normal old individuals, Alzheimer-type dementia and ocular cataracts are usually not seen. Malignancies are also not commonly seen in HGPS, perhaps because they die at such early ages.

HGPS is caused by mutations in *LMNA*, which encodes nuclear intermediate filaments, lamin A and C (139,140). Lamin A and C, generated by alternative splicing of *LMNA*, undergo dimerization and head-to-tail assembly to form nuclear lamina that lies on the inner surface of the inner nuclear membrane (141). Point mutations within *LMNA* exon 11 found in HGPS create a cryptic splicing site and generate a 50 amino acid in-frame deletion that includes the proteolytic site required for the maturation of prelamin A to lamin A (139,140). Unlike wild-type lamin A, this in-frame deletion mutant, termed progerin, retains the farnesyl moiety at its C-terminus. The resulting accumulation of progerin is thought to be responsible for the phenotypic presentation of HGPS (142). At a cellular level, the presence of progerin is shown to cause structural abnormalities and/or fragility of nuclei (143), aberrant reorganization of the heterochromatin and epigenetic changes (144), genomic instability (145),

FIGURE 18-7 Hutchinson–Gilford progeria syndrome. (Courtesy of the Progeria Research Foundation.)

and impaired telomere maintenance (146). Age-associated accumulation of very small amount of progerin has been demonstrated in human, suggesting the possibility that progerin may be, in part, involved in development of the age-related pathologies in normal individuals (138,147).

LMNA mutations are also responsible for a group of disorders, termed laminopathies, including Emery–Dreifuss muscular dystrophy, dilated cardiomyopathy type 1A (DCM1A) with or without atrio-ventricular conduction disturbance, limb-girdle muscular dystrophy type 1B (LGMD1B), Charcot–Marie–Tooth disease type 2 (CMT2), Dunnigan-type familial partial lipodystrophy, mandibuloacral dysplasia, atypical forms of WS, and restrictive dermopathy (RD) (148). With the exception of RD and HGPS, the majority of LMNA mutations found in these disorders are amino acid substitutions instead of in-frame deletions.

Farnesyltransferase inhibitors have been shown to ameliorate HGPS phenotypes in cell cultures and in mouse models (149,150). Clinical trials are ongoing. The rationale for this approach has been challenged, however, by the finding that non-farnesylated progerin can elicit HGPS-like phenotypes in mice (151).

### 18.5.3 HUMAN ALLELIC VARIANTS HOMOLOGOUS TO PRO-LONGEVITY GENES IN MODEL ORGANISMS

There has been a surge of interest in testing the hypothesis that the ability to achieve remarkable longevity in centenarians is due to the inheritance of alleles at a few loci of major relevance. A priori, one would predict that such research would be quite risky, given the arguments made earlier in this chapter that life span is under highly polygenic modulations and that it is also determined, in part, by stochastic events. It is the case, however, also noted above, that atherosclerosis (and the associated heart attacks and strokes) is a major limitation of human life span in the developed societies. Therefore, it is perhaps not surprising that an association of unusual longevity with variant alleles for lipoprotein metabolism has been observed (152). More recent studies demonstrated the association of polymorphisms in the forkhead box class O (FOXO) family of transcription factors among several independent centenarian populations (153). The FOXO genes are key regulators of the insulin-IGF1 signalling pathway (Figure 18-5).

There is also considerable interest lately in Laron dwarfism because of their mutations in the growth hormone pathway (154,155). People with Laron dwarfism in the Ecuadorian villages are resistant to cancer and diabetes and are somewhat protected against aging. This is consistent with findings in mice with a defective growth hormone receptor gene, suggesting this “public mechanism” of aging may apply to our species (156).

### 19.1 INTRODUCTION

*Pharmacogenetics* is defined as “the study of heritable variability in drug response (168),” or simply, “gene–drug interactions.” Responses to drugs often differ among individuals. Each person has his own unique “pharmacogenetic profile”—just as each of us has our own distinct pattern of microsatellite differences, single nucleotide polymorphisms (SNPs), or thumbprint. Our genetic makeup largely determines our drug response. Drug response is very complex, however, and includes (a) numerous events associated with genomic differences (some known, others not yet understood), (b) many environmental effects (e.g. diet, cigarette smoking, drug–drug interactions, and exposure to occupational chemicals and other environmental pollutants), and (c) endogenous factors (e.g. age, gender, exercise, various disease states, status of renal function, function of other organs, etc.).

*Pharmacogenomics* is defined (23) as “the study of how drugs interact with the *total genome*, to influence biological pathways and processes.” This field, a direct by-product of The Human Genome Project, might help in identifying new drug targets and, thus, in designing new drugs. The terms pharmacogenetics and pharmacogenomics are often used interchangeably, but they should not be.

Recently, pharmacogenetics/pharmacogenomics has become synonymous with “*individualized drug therapy*,” a major subset within the broader field of “*personalized medicine*.”

The field of pharmacogenomics has expanded enormously in the past two decades; therefore, this chapter represents “a snapshot in time.” The breakneck speed

of publications in this area of research includes results of high-throughput large-cohort studies, new data from genome-wide association (GWA) studies, and the very recent “1000 Genomes Project,” whole exome sequencing, and “next-generation deep resequencing” studies. As our knowledge of the human genome expands, our comprehension of pharmacogenomics will continue to grow.

#### 19.1.1 Definition of Adverse Drug Reactions

*Adverse drug reactions (ADRs)* rank as approximately the fifth leading cause of death in the United States (85). ADRs include dose-dependent reactions, dose-independent reactions (including idiosyncratic drug reactions and allergic reactions), dose- and time-dependent reactions (cumulative), time-related reactions, and withdrawal reactions (31). Advances in pharmacogenetics and pharmacogenomics should help to reduce the morbidity and mortality caused by *idiosyncratic dose-independent drug reactions*.

#### 19.1.2 Definition of Allelic Variants

Each gene has two alleles on a chromosome pair—one from each parent. A minor allele having a frequency of  $\geq 0.05$  (5%) is termed a *common variant*. A minor allele having a frequency of  $\geq 0.01$  is called a *polymorphic variant*, and a minor allele with a frequency of  $< 0.01$  is termed a *rare variant*. The Hardy–Weinberg equilibrium (HWE), “ $p^2 + 2pq + q^2 = 1$ ” was originally developed to describe the frequencies of  $p$ , the wild-type trait, and  $q$ , the mutant

(or variant) trait. From the 1860s until the late 1980s, it was thought that there would be (for any gene) only one wild-type allele and only a few variant alleles.

If  $q = 0.01$ , the percentage of individuals homozygous for an autosomal recessive trait will be  $q^2$ , i.e. 1 in 10,000. Owing to previous difficulties in studying populations of 10,000 or greater, for most clinical studies, the lowest frequency of a variant allele usually investigated has been 0.05, i.e. common variants. During the past several years, cohorts have become larger, and interest has now been focused on alleles with frequencies between 0.01 and 0.05. At present, one cohort of 500,000 subjects, with height as the phenotype, is being studied. After it became appreciated in the late 1980s that multiple alleles exist for every gene (124),  $q$  is now considered the sum of all variant alleles.

The term  $q$  has been replaced by MAF (minor allele frequency), referring to “the frequency at which all biallelic SNP alleles other than the major allele occur in a given population.” An additional complexity is that the so-called wild-type (or “major,” or “consensus”) allele in one ethnic population might be a minor allele in ethnically different populations. For example, when 313 genes in 82 unrelated individuals of five geographically isolated subgroups were examined, more than one-third of the selected genes had no major allele with a frequency exceeding 50% (149).

### 19.1.3 Individualized Drug Therapy

Can we design DNA tests that will predict how a patient will respond to any particular drug—with close to 100% degree of certainty? This is what the physician wishes to know: which patient will benefit from drug efficacy vs which patient will develop an ADR or therapeutic failure? This approach has become very popular during the past two decades, and, indeed, some scientists still believe in this lofty goal. Innumerable publications have predicted that such DNA tests are here or will very soon become mainstream. However, the purpose of this chapter is to describe some of the complexities now known to exist in the human genome. We can then use that knowledge to make a distinction between “predictions of plasma or urine levels of a drug or metabolite or therapeutic failure” vs “predictions of ADRs or drug efficacy”; the former reflects a high-penetrance predominantly monogenic (hPpM) trait (124), whereas the latter (vide infra) is usually as complicated and heterogeneous as any human “complex disease” (e.g. obesity, schizophrenia, pancreatitis, seizures, stroke, coronary artery disease, or type 2 diabetes).

The US Food and Drug Administration (FDA) recommends that all physicians genotype their patients for specific biomarkers—before prescribing currently more than 70 different medications. The FDA suggests that these genetic biomarkers might help physicians identify patients in whom these commonly used drugs would be “less efficacious, insufficiently metabolized, or toxic.” In recent surveys, most physicians agree that genetic profiles of patients can affect drug therapy, but only approximately 10% of physicians believe they have been adequately

informed about using such genetic biomarkers in patients; accordingly, few physicians actually order these tests.

Furthermore, few physicians appreciate the actual range of increased risk associated with positive results of these tests—a range of approximately only 1.8- to 2-fold. Several reasons account for this lack of genomics testing usage and implementation; these include the need to demonstrate more clearly and unequivocally clinical utility as well as bombardment of physicians with a continuous, bewildering, and indigestible volume of new genomics information. Often genomics testing results are irreproducible or they vary between different ethnic populations and make insurance reimbursements problematic. Therefore, individualized drug therapy or personalized medicine based entirely on genomic testing is now far from being a clinical reality, or even becoming so soon.

### 19.1.4 Organization of this Chapter

First, several fundamental aspects of clinical pharmacology are reviewed, followed by a brief summary of classical *human monogenic diseases* and then several classical *human hPpM* pharmacogenetic disorders. We then point out the importance of *ethnic differences* in these hPpM traits and the likelihood that interethnic variability is a feature that reflects human migration and geographic isolation over tens of thousands of years.

The latter half of the chapter is devoted to advances in genomics during the past two decades, which are relevant to the field of pharmacogenomics. We propose that drug efficacy, as well as ADRs involving drug toxicity, in most cases are conceptually the same as *human complex diseases*. We now realize that to understand drug efficacy and ADRs, we can apply all the same novel human genomics methodologies—now being carried out in the study of complex diseases—to the field of pharmacogenomics.

## 19.2 FUNDAMENTAL ASPECTS OF CLINICAL PHARMACOLOGY

The clinical pharmacologist’s objective of treating a patient with a drug is to maintain optimal plasma levels of the active principle (drug) in the *therapeutic range* (Figure 19-1). If the dose of the drug is too small, the interval of administration inadequate, bioavailability of the drug product low, or the active principle extensively metabolized and quickly excreted—the plasma drug level might not reach the minimal effective concentration. This would lead to the absence of the expected response (*therapeutic failure*). On the contrary, if the dose of drug is too large, its interval of administration too short, or the active principle poorly metabolized or excreted, the drug can reach *toxic levels*. Levels that cause toxicity will lead to ADRs; these *multiplex phenotypes* will occur due to drug accumulation at toxic levels in blood as well as in one or more critical target organs.

These scenarios exist if the *parent drug* is the one responsible for efficacy as well as toxicity. If a *metabolite* is the active principle (i.e. that which causes efficacy) and

**FIGURE 19-1** Theoretical plasma concentration curves for any drug, as a function of time after oral administration of the dose. In this hypothetical case, the horizontal line (at 10 µg/mL) is the minimum effective concentration and the horizontal line (at 20 µg/mL) is the minimum toxic concentration.

also the toxicant, then one can replace the word “drug” with “metabolite” and describe the same events leading to *efficacy vs therapeutic failure vs toxic levels* (124).

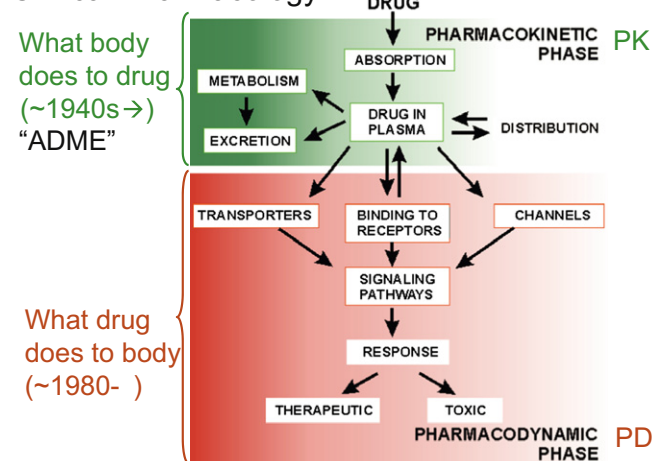

### 19.2.1 Pharmacokinetics and Pharmacodynamics

Pharmacokinetics (PK) represents what the body does to the drug, whereas pharmacodynamics (PD) reflects what the drug does to the target tissues (Figure 19-2). The end result of all PK and PD processes is therapeutic failure, drug efficacy, or toxicity (ADRs); the latter two outcomes represent processes usually conceptually the same as complex diseases.

Variations in the drug’s PK phase encompass the processes of *absorption, distribution, metabolism, and excretion*, which pharmaceutical companies commonly describe as ADME. PK differences are generally detected by determinations of the active drug (or metabolites) in blood and less often by urinary (or saliva, sweat, fecal) determinations. For most systemic drugs, the concentration of the (unbound or free) active principle in blood is proportional to the concentration of active principle in the target tissue. Most of the pharmacogenetic differences that had been initially reported involved genes participating in drug metabolism. More recently, pharmacogenetic differences were reported in genes participating in distribution (binding, transport), absorption, and excretion.

Variations in the PD phase occur “downstream” of the PK phase (Figure 19-2). Thus, gene differences might be seen in transporters and channels across the different membranes of the cell; receptors at the cell surface, in other intracellular membranes, and in the cytosol and the nucleus; tissue- and cell-type-specific transcription factors (TFs) and signal transduction pathways; nucleic acid and protein repair processes;

### Clinical Pharmacology:

**FIGURE 19-2** Basis of clinical pharmacology. The processes involve the *pharmacokinetic* (PK) phase and the *pharmacodynamic* (PD) phase—of any drug or over-the-counter preparation.

chaperones; and cell infrastructure (e.g. nuclear matrix, membranes, and subcellular organelles such as Golgi bodies, melanosomes, or peroxisomes). Until the 1980s, what happened in the PD phase was largely considered a “black box.” Owing to rapid advances in molecular biology, downstream drug signaling pathways have now become better understood and the field of PD has exploded (124).

Historically, drugs or chemicals were given to human volunteers or laboratory animals and differences in urinary metabolite profiles were determined (e.g. (12,175)). Next, variations in laboratory animals (164) and in clinical PK (166)—reflected as differences in plasma drug levels or clearance—led to the elucidation of genetic variability in drug metabolizing enzymes (DMEs). This occurred in human volunteers or patients because blood samples were easier to obtain than tissue biopsies. Also, this happened at the laboratory bench because enzyme assays were especially popular between the 1940s and 1980s.

With advances in molecular biology methodologies and then the explosion in knowledge derived from The Human Genome Project, elucidation of genetic differences in measurements other than DME assays has become more commonplace. For example, receptor assays began in the late 1970s and developed during the 1980s, transporter and ion channel assays were initiated in the 1980s and became popular in the 1990s, and analyses of signal transduction pathways, post-translational modifications, and many other subcellular processes have greatly expanded during the past two decades. Another consideration in the 1980s and 1990s was that DME genes are in general smaller, spanning approximately 5–20 kb, whereas receptor and transporter genes are usually approximately 50–>100 kb in length; the cloning, sequencing and characterization of DME genes therefore was technically easier than for the much larger genes.

### Therapeutic “Window”

$$\frac{\text{Toxic dose (TD}_{50}\text{)}}{\text{Effective dose (ED}_{50}\text{)}} = 20 \text{ [large window] A}$$

$$\frac{\text{Toxic dose (TD}_{50}\text{)}}{\text{Effective dose (ED}_{50}\text{)}} = 2 \text{ [narrow window] B}$$

- If genetic differences in drug response are 10-fold then drug A → no problem; drug B → ADRs

**FIGURE 19-3** Simple equations illustrating what represents a large vs a small therapeutic “window” or index.

### 19.2.2 Therapeutic Index (or “Window”)

Most pharmacogenetic studies owe their success to the selection of study drugs having narrow therapeutic indices. If a drug shows a wide therapeutic window, it is unlikely to cause toxicity in a significant portion of any human population; therefore, this would be of little concern to public health, and the need to prevent ADRs would be small. For example, if the dose causing toxicity is 20 times greater than the dose needed to be effective (Figure 19-3), and genetic differences in handling this drug are never greater than 10-fold across human populations, this drug would be of little concern to a pharmacogeneticist. On the other hand, if the dose causing toxicity is only twice the dose for efficacy, and pharmacogenetic differences in handling this drug are 10-fold, this drug could be an important candidate to study in order to understand ADRs that might lead to morbidity and mortality.

## 19.3 CLASSICAL GENETICS AND PHARMACOGENETICS: 1900 TO APPROXIMATELY 1990

### 19.3.1 Human Monogenic Diseases

In human genetics, from Sir Archibald Garrod in the first decade of the twentieth century through the late 1980s, it was believed that humans—like insects, plants, or yeast—had only one “wild-type” allele and only a few mutant (or variant) alleles (116). Cloning and sequencing of the phenylalanine hydroxylase consensus gene (*PAH*) in a heterozygous carrier of phenylketonuria (PKU) constituted a major landmark because it identified the first mutation (first nucleotide of intron 12) responsible for a human monogenic disease (27). Following additional sequencing studies, it became apparent that different mutations in the same gene (genotype) caused the same disease (phenotype); this phenomenon is termed *allelic heterogeneity*. At present more than 500 *PAH* mutations have been recorded that result in “the PKU phenotype.”

However, virtually no disease reflects a truly monogenic trait; from the earliest autosomal recessive *monogenic disorders* described by Garrod (e.g. alkaptonuria and cystinuria) to cystic fibrosis caused by mutations

in the *CFTR* gene, the onset and severity of symptoms were realized to be affected by *modifier genes* (52,182) as well as environmental factors (116). For example, severe forms of PKU become expressed during early infancy, whereas a milder form of PKU might present in late childhood or adolescence. Also, the same missense mutation in the coding region of the acid-β-glucosidase gene (*GBA*) can cause debilitating Gaucher disease—presenting as massive hepatosplenomegaly, mental retardation, and death before the age of 10 years in the proband—while the grandfather of the proband might show only mild signs of the disease such as slight hepatosplenomegaly, and yet live into his 70s.

### 19.3.2 hPpM Traits

Variations among individuals in PK and sometimes PD (Figure 19-2) usually represent hPpM traits. These genetic differences can range from approximately 2- to more than 100-fold. Examples of hPpM traits include dramatic differences in metabolism or transporter function, e.g. *N*-acetyltransferase, debrisoquine oxidation, thiopurine methyltransferase (*TPMT*), and glutathione *S*-transferase activities; ATP-binding cassette (ABC) and solute-carrier (SLC) transporters; and G-protein-coupled receptor (GPR) functions. Table 19-1 includes a list of various hPpM traits and disorders. Note that most early discoveries reflected metabolism gene deficiencies, whereas the latter ones began to represent transporter gene defects.

### 19.3.3 Drug Metabolism Enzymes and DME-Related Transporters

The human genome contains hundreds of metabolism genes. Virtually all drugs are metabolized by Phase I DMEs (*functionalization*), followed by Phase II (*conjugation*) DMEs (Figure 19-4). Phase I DMEs insert or activate a functional (generally polar) group on the drug. One major class of Phase I DMEs comprise the cytochromes P450 (CYPs), probably the most thoroughly studied of all pharmacologically relevant enzymes. There are 57 human *CYP* genes, compared with, for example, 103 mouse and 89 rat *Cyp* protein-coding genes [<http://drnelson.uthsc.edu/>]. Five human P450 enzymes (CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP3A5) metabolize more than 80% of all commonly prescribed and over-the-counter medications. Each of five additional P450 enzymes also metabolize another few dozen drugs: CYP1A2, CYP2A6, CYP2B6, CYP2E1, and CYP4A11 [<http://medicine.iupui.edu/clin-pharm/ddis/table.asp>]. Seven P450 enzymes are primarily responsible for detoxifying (in some cases) or metabolically activating (in other cases) environmental carcinogens: CYP1A1, CYP1A2, CYP1B1, CYP2B6, CYP2E1, CYP3A4, and CYP3A5 (134). Other Phase I DMEs include flavin-containing monooxygenases (FMOs), hydroxylases, hydrolases, esterases, galactosidases, glycosidases, peroxidases, lipooxygenases, cyclooxygenases, monoamine oxidases, dioxygenases, reductases, and dehydrogenases.

**TABLE 19-1** Predominantly Monogenic Pharmacogenetic Disorders That Have Been Characterized<sup>a</sup>

Disorder	Major Gene Known to be Responsible	Pivotal Reference(s)
Phenylthiourea–nontaster	<i>TAS2R1</i>	(77,146)
Hypocatalasemia	<i>CAT</i>	(154)
Atypical serum cholinesterase	<i>BCHE</i>	(72)
Glucose-6-phosphate dehydrogenase deficiency	<i>G6PD</i>	(102)
Isoniazid slow <i>N</i> -acetylation	<i>NAT2</i>	(9,36)
Fish odor syndrome (trimethylaminuria)	<i>FMO3</i>	(58,62)
Debrisoquine/sparteine oxidation poor metabolizer	<i>CYP2D6</i>	(32,47,97)
Serum paraoxonase low activity	<i>PON1</i>	(63,170)
Thiopurine methyltransferase deficiency	<i>TPMT</i>	(177)
Sensitivity to alcohol	<i>ALDH2</i>	(158)
<i>S</i> -mephenytoin oxidation deficiency	<i>CYP2C19</i>	(25,81)
Sulfotransferase deficiency	<i>SULT1A1</i> , <i>SULT1A2</i>	(176)
Coumarin, nicotine oxidase deficiency	<i>CYP2A6</i>	(184)
P-glycoprotein transporter defect	<i>ABCB1</i>	(78)
Malignant hyperthermia	<i>RYR1</i>	(96)
Quinone oxidoreductase defect	<i>NQO1</i>	(161)
Peptide transporter defect	<i>TAP2</i>	(132)
Phenytoin, warfarin oxidation defect	<i>CYP2C9</i>	(24)
Debrisoquine ultrametabolizers	<i>CYP2D6</i> *1XN	(69)
Epoxide hydrolase deficiency	<i>EPHX1</i>	(51)
Glutathione <i>S</i> -transferase null alleles	<i>GSTM1</i> *0, <i>GSTT1</i> *0	(76,178)
Long-QT syndrome	<i>KCNH2</i>	(19)
Dihydropyrimidine dehydrogenase deficiency	<i>DPYD</i>	(105)
Chlorzoxazone hydroxylation defect	<i>CYP2E1</i>	(60)
Peptide transporter defect	<i>TAP1</i>	(133)
Sulfonylurea receptor defect	<i>ABCC8</i>	(177)
Calcium channel defect	<i>CACNA1A</i>	(187)
Androstane glucuronosyl conjugation	<i>UGT2B4</i>	(88)
Congenital long-QT syndrome	<i>SCN5A</i>	(174)
<i>S</i> -oxazepam glucuronosyl conjugation	<i>UGT2B7</i>	(150)
Paclitaxel hydroxylase deficiency	<i>CYP2C8</i>	(21)
Chlorpyrifos oxidation deficiency	<i>CYP3A4</i>	(20)
Acrodermatitis enteropathica	<i>SLC39A4</i>	(171)
Nifedipine oxidation deficiency	<i>CYP3A5</i>	(86)
Cyclophosphamide metabolism deficiency	<i>CYP2B6</i>	(82)
Hyperinsulinemic hypoglycemia	<i>SLC16A1</i>	(129)
Hereditary folate malabsorption	<i>SLC46A1</i>	(189)

<sup>a</sup>This list is not meant to be all-inclusive. In each case, compared with the consensus allele, one or more variant alleles lead to a defective gene product, resulting in decreased metabolism, transporter or receptor activity, or channel function. The clinical consequence in most homozygous affected subjects is toxicity, because of drug accumulation with enhanced drug activity. Occasionally, decreased drug activity (*therapeutic failure*) ensues if the variant reflects ultrarapid drug metabolism or if, for activity, the drug requires metabolic conversion to an active form and this conversion is decreased in the variant. We realize that some of the traits listed here might concern primarily environmental toxicants (e.g. *TAS2R1*, *CAT*, *FMO3*, and *PON1*) rather than prescribed drugs.

Phase II DMEs conjugate the Phase I products, usually inserting a highly polar conjugation moiety on a somewhat polar moiety produced by Phase I enzymes (Figure 19-4). Examples of Phase II DMEs include glucuronosyl, sulfate, glutathione, glycosyl, acyl, glycine, amine, acetyl, and methyl transferases. Drug metabolism research for the past six decades focused largely on these Phase I and Phase II DMEs.

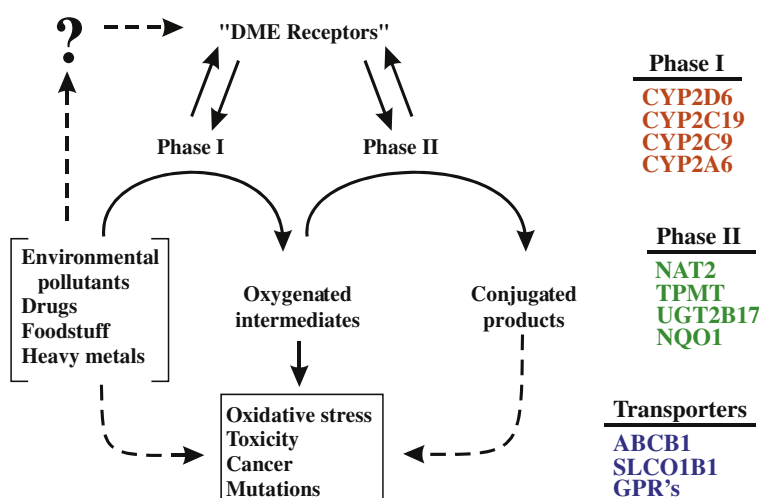

### 19.3.4 Plasma Clearance of Drug

In the late 1960s, comparisons of drug clearances in monozygotic vs dizygotic twins were reported. The “heritability index” was calculated as the variance within pairs

of dizygotic twins ( $V_d$ ) minus the variance within pairs of monozygotic twins ( $V_m$ ) divided by  $V_d$ . A heritability index of 1.0 would represent “purely genetic,” whereas a heritability index of less than 0.50 would indicate “predominantly environmental” factors. From twin studies (of dicoumarol, phenylbutazone, desipramine, halothane, nortryptiline, oxyphenylbutazone, and antipyrine), the main conclusion was that large variations among healthy subjects in drug clearance rates reflect a strong genetic component (165). Four decades later, we can appreciate that these observations reveal, principally, allelic differences in a few DME and/or DME-Related Transporters (DRTs) genes. Thus, “rapid” and “slow” Phase I and Phase II DME metabolism, respectively, plus “efficient”

### hPpM genes encode DMEs or drug-related transporters

**FIGURE 19-4** Scheme of Phase I and Phase II drug metabolizing enzymes (DMEs), the DME Receptors that Up- and Downregulate DME Levels, and DME-related transporters (DRTs) that move drugs and metabolites in and out of the cells, as well as across internal cell membranes. Certain environmental pollutants, drugs, foodstuff, and heavy metals interact with DME receptors, or other (reception) pathways, to up- or downregulate DME gene expression. (Modified from Reference (120)).

and “defective” DRT function, are among the principal effectors of plasma drug and metabolite clearance and therapeutic failure. These results underscore one of the themes of this chapter: that some pharmacogenetic differences—including large variability among normal subjects in plasma and urine drug and metabolite levels—can reflect polymorphisms in one or a few hPpM genes.

### 19.3.5 Extrahepatic Pharmacogenetic Differences and Endogenous Functions of DME

A common misconception is that DMEs exist almost exclusively in the liver. A corollary is that only drugs, and not endogenous compounds, are substrates for DMEs. Both statements are incorrect (111,114). CYP3A4, the most abundant P450 in liver, is also present in large concentrations in the gastrointestinal tract. Many DMEs are located in the lung and kidney. Many Phase I and Phase II DMEs exist in all vascular endothelial cells and contribute to the expression of the arachidonic acid cascade and thus eicosanoid synthesis and degradation; the result is effects on cell division, inflammatory response, cell migration, bronchoconstriction, vasodilation, and numerous other homeostatic mechanisms (119). Because DMEs exist in the choroid plexus, substantia nigra, vasculature, and basically any other cell type of the brain, they play pivotal roles in neuroendocrine functions. CYP2D6, encoding a major P450 that metabolizes drugs in the liver, is responsible for serotonin synthesis in the brain (186). Phenytoin oxidation (principally due to CYP2C9 and CYP2C19) is as much as 50-fold greater in human oral mucosa than liver (191). Some DMEs exist at high concentrations in nasal mucosa (48). Clinical geneticists

must recognize that variability in drug response can occur in any tissue and any cell type, not solely in the liver.

It is doubtful whether any DME exists that metabolizes only drugs without endogenous function (111,121). When an hPpM variant leads to an absent DME activity in a human, the clinical equivalent of a “knockout mouse,” one might ask—if the DME carries out, in addition to drug metabolism, one or more “critical life functions”—why is there usually no phenotype of illness or lethality? Actually, the same result (i.e. no striking change in phenotype) has been observed in numerous hPpM knockout mouse lines after genes encoding DMEs, receptors, DRTs, or other moieties have been disrupted. The answer is that Mother Nature most likely has incorporated a great deal of *redundancy*, beneficial for survival of the species.

### 19.3.6 Examples of hPpM Pharmacogenetic Polymorphisms

What follows are several examples of hPpM variants. Owing to space limitations, only a few cases will be described, but most remaining examples in Table 19-1 have been reviewed extensively [(117,118) and references therein].

**19.3.6.1 N-Acetylation Polymorphism (NAT2 Gene).** Originally called the “isoniazid acetylation polymorphism,” this defect was identified in the late 1940s when patients who converted to a positive tuberculin test routinely received isoniazid. A high incidence of peripheral neuropathy was noted. This is an example of the active principle (parent drug) reaching toxic levels (Figure 19-1) when the major detoxication enzyme in the isoniazid metabolic pathway is defective.

After isoniazid was administered to different individuals and their plasma isoniazid levels measured (Figure 19-5),

## Isoniazid 9.8 mg/kg, plasma levels 6 h later

---Br Med J 1960; 2: 485

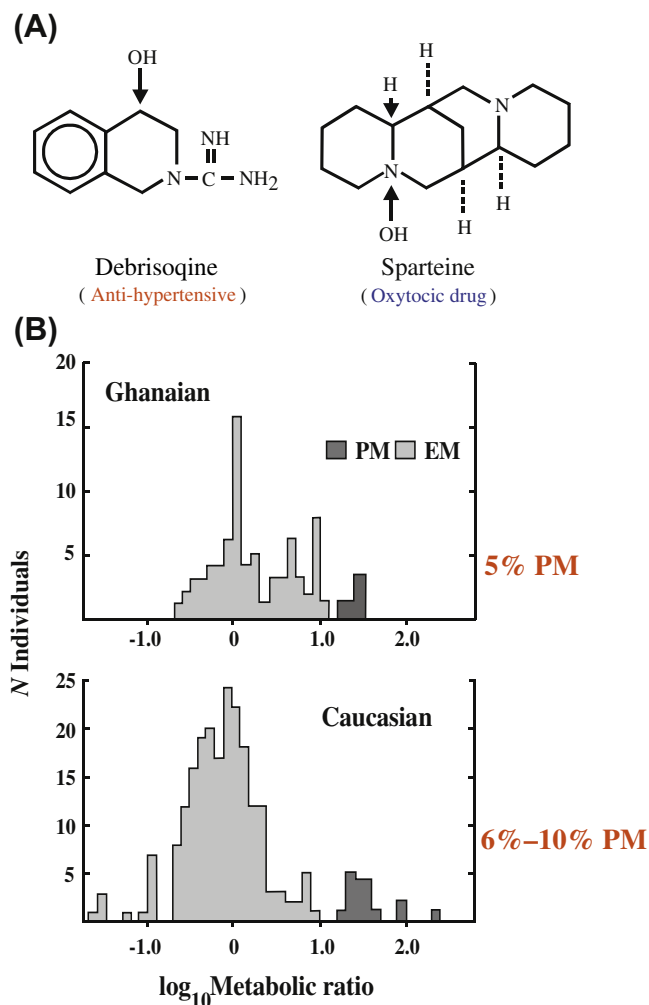

**FIGURE 19-5** Plasma isoniazid concentrations 6h after the drug was given. Results were obtained in 267 members of 53 complete family units. All subjects received 9.8mg isoniazid per kilogram body weight. (Redrawn from Reference (36)).

a *bimodal distribution* was described (36). Individuals were phenotyped as “slow-acetylators” or “rapid acetylators” (slow vs rapid plasma clearance). Parents of slow-acetylator children were also slow acetylators—indicating that slow acetylators are homozygous for the “slow-acetylator” allele (*r*), whereas rapid acetylators are either heterozygous or homozygous for the “rapid” (*R*) allele. Hence, the *slow phenotype* is inherited as an *autosomal recessive* trait. Frequency of the *r* allele was approximately 0.72 in the 1959 United States population (36); using the Hardy–Weinberg Equilibrium equation, this means that about one in every two individuals in this population is homozygous for *r/r*, reflecting the slow-acetylator trait.

Isoniazid *N*-acetyltransferase is an example of a Phase II DME polymorphism (Figure 19-4). Two human *N*-acetyltransferase protein-coding genes (*NAT1*, *NAT2*) are located in tandem on chromosome (Chr) 8p22. Rapid- and slow-acetylator phenotypes reflect the *NAT2* gene, encoding the *NAT2* enzyme, which has a 10-times-lower  $K_m$  than *NAT1*, using isoniazid and other arylamine substrates. Several *NAT2* slow-acetylator variant alleles encode a stable protein having little or no enzymatic activity or an unstable protein (9). A consensus nomenclature for the *NAT1* and *NAT2* alleles was developed in 1995 and is still updated online [<http://louisville.edu/medschool/pharmacology/consensus-human-arylamine-n-acetyltransferase-gene-nomenclature/>]. The (rapid-acetylator) consensus allele is *NAT2*\*4; presently, there are 63 alleles identified.

**19.3.6.2 Debrisoquine/Sparteine Oxidation Polymorphism (CYP2D6 Gene).** In the mid-1970s, the debrisoquine/sparteine polymorphism (Figure 19-6A) was discovered independently by two groups. The Robert L Smith laboratory in England (4) studied oxidative metabolism of the antihypertensive agent, debrisoquine. Smith noticed that, soon after its release in the United Kingdom,

**FIGURE 19-6** Illustration of the *CYP2D6* polymorphism. (A) Structures and major metabolites of debrisoquine and sparteine. (B) Frequency of the efficient (EM)- and poor (PM)-metabolizer phenotypes in populations from Ghana and Caucasians in the United Kingdom. Urinary “metabolic ratio” (MR) = parent drug debrisoquine divided by hydroxylated debrisoquine metabolites; because PM individuals show less metabolism, this ratio places PM subjects to the *right* of EM subjects. (Redrawn from Reference (193)).

debrisoquine caused a high incidence of ADRs; he reasoned that the combination of a narrow therapeutic index (described earlier, Figure 19-3) with an underlying genetic variation in metabolism might be responsible. Smith and three laboratory colleagues took the “recommended prescribed” dose of debrisoquine. Smith himself became hypotensive; his urinary 4-hydroxy metabolite was about 20-fold lower than that of his three colleagues who appeared unaffected by that dose. This is another example of a pharmacologically active drug reaching toxic levels because of insufficient metabolism to an inactive metabolite (Figure 19-1). A larger population was screened, and a *bimodal distribution*, separating “poor-metabolizer” (PM) subjects from “extensive-metabolizer” (EM) subjects.

Michel Eichelbaum for his 1975 thesis work in the Dengler laboratory in Germany studied human metabolism of the oxytocic drug, sparteine. This drug was

known to cause erratic and excessive uterine contractions in women; the urinary ratio of sparteine to dehydrosparteines showed a bimodal distribution (33). This variability in debrisoquine/sparteine metabolism is another example of a Phase I DME polymorphism.

The PM phenotype for debrisoquine occurs in 6–10% of people of European descent (Figure 19-6B, *bottom right*), compared with EM phenotype subjects who metabolize the drug 10–50 times more effectively (64). Incidence of the PM phenotype is approximately 5% in African populations (Figure 19-6B, *upper right*) and <1% in Asians. An “ultrarapid metabolizer” (UM) phenotype was also described; this phenotype was found to be due to amplification of the *CYP2D6* gene from 2, to as many as 13, copies (107). Incidence of the UM phenotype is about 0.8% in Northern Europeans, 21% in Saudi Arabians, and 29% in Ethiopians (65); the reason for these ethnic differences is not known but is likely to be the result of some selective pressure (probably dietary) or of a genetic bottleneck.

The P450 enzyme responsible for the debrisoquine/sparteine polymorphism is *CYP2D6*, a Phase I enzyme. Cloning of the *CYP2D6* genes and characterization of several mutant alleles (47) represented a landmark study providing for the first time a molecular mechanism to explain a descriptive pharmacogenetics disorder. PM alleles can code for an inactive enzyme because of mutation, unstable protein, incorrect splicing of the gene transcript, or even complete deletion of the gene—resulting in lowered, or completely absent, enzyme activity.

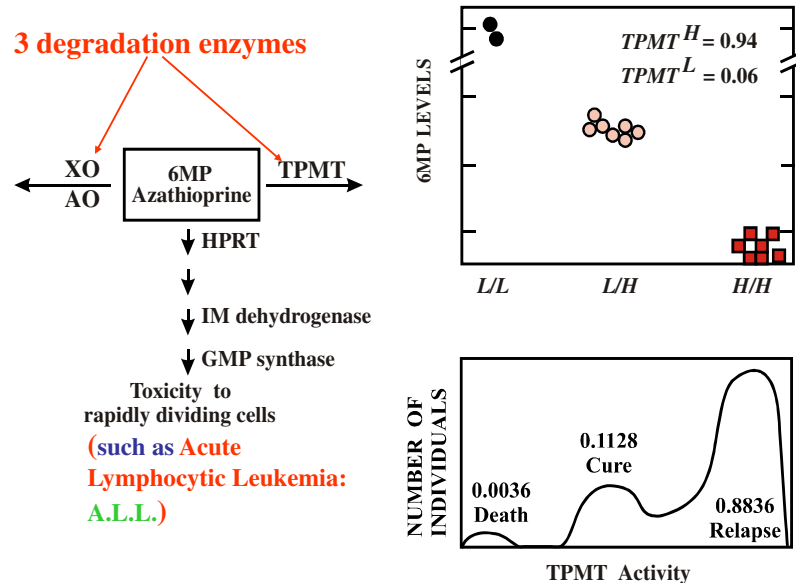

A unified system for naming human *CYP2D6* alleles is now used for allelic nomenclature of many human genes. The *CYP2D6*\*1 allele is the consensus, or reference, sequence (wild-type, EM); and currently, 126

allelic variants or haplotypes, plus 11 additional variants in which the haplotype is not yet understood, have been reported [<http://www.cypalleles.ki.se/cyp2d6.htm>].

The *CYP2D6* polymorphism is important in elimination of >20% of all commonly prescribed drugs, as well as over-the-counter drugs. The debrisoquine “panel” now comprises more than eight dozen drugs: tricyclics and other antidepressants including serotonin reuptake inhibitors and monoamine oxidase inhibitors, neuroleptics, antiarrhythmics and antihypertensives (including  $\beta$ -blockers), and opiates [<http://medicine.iupui.edu/clin-pharm/ddis/table.asp>].

**19.3.6.3 TPMT Polymorphism.** TPMT is a Phase II enzyme with a major role in the detoxication of 6-mercaptopurine (6MP), commonly used in chemotherapy for childhood acute lymphocytic leukemia. In the original study of a Caucasian cohort (177), frequencies of *high/high*, *high/low*, and *low/low* phenotypes were reported as approximately 88%, approximately 11%, and approximately 0.4%, respectively. This means that, when the “commonly recommended prescribed dose” of 6MP is given, 11% of patients would have a high probability of being cured of their disease, 88% would have relapses in their leukemia due to undertreatment, and one of approximately 300 patients might die from 6MP toxicity (Figure 19-7). In other words, if metabolism of 6MP is too extensive in 88% of patients, *therapeutic failure* (illustrated in Figure 19-1) may ensue.

This pharmacogenetic disorder is very dramatic, because it can lead to life-or-death clinical situations. Accordingly, in 1994, the *TPMT* polymorphism was presented to the US Congress as “the quintessential pharmacogenetic disorder” on the basis of which more federal funding was

**FIGURE 19-7** Diagram of 6-mercaptopurine (6MP), azathioprine or 6-thioguanine toxicity (which occurs in all cells but more so in rapidly dividing cells such as acute lymphocytic leukemia (ALL) white cells, due to disruption of purine biosynthesis), and the response of ALL patients given the “commonly recommended” prescribed dose of 6MP. Xanthine dehydrogenase (XO encoded by the *XDH* gene), adenine oxidases-1 and -2 (AO encoded by the *DUOX1* and *DUOX2* genes), and TPMT (thiopurine methyltransferase) are all enzymes that detoxify these chemotherapeutic drugs. Toxicity of these agents occurs more readily in *TPMT*<sup>L/L</sup> individuals than in *TPMT*<sup>H/H</sup> individuals. About 3 in 1000 Caucasians are homozygous for the L/L phenotype, 13% are heterozygotes, and 88% are homozygous for the H/H phenotype.

requested for pharmacogenetics research. Because the TPMT defect can lead to dire consequences, patients with acute lymphocytic leukemia (ALL) are now routinely phenotyped for red cell TPMT activity prior to initiation of 6MP chemotherapy. *TPMT<sup>HH</sup>* patients are usually given a four times larger dose, and *TPMT<sup>LL</sup>* patients are given a 10- to 15-times smaller dose—leading to a much better cure rate and survival rate for childhood leukemia.

The *TPMT* gene has nine exons, spanning 26.8kb. A total of 29 allelic variants have been identified (5), in each case resulting in very low or negligible catalytic activity.

Azathioprine and 6-thioguanine are other TPMT substrates (Figure 19-7). Azathioprine is widely used as an immunosuppressant in conditions as diverse as systemic lupus erythematosus and organ transplantation. Thioguanine is one of the agents used in treating chronic myelocytic leukemia. As with 6MP, azathioprine or 6-thioguanine can be lethal to the one-in-300 patient with homozygous *TPMT<sup>LL</sup>* if that subject receives the “commonly recommended prescribed” dose.

**19.3.6.4 Glutathione S-Transferase Polymorphisms (GST Genes).** GSTs are Phase II enzymes that add glutathione to many drugs and chemical metabolites. High GST activity can lead to rapid detoxication rates of antibiotics and chemotherapeutic agents (160). Usually considered Phase II detoxication enzymes (Figure 19-4), GSTs can also be involved in metabolic activation (109). The *GST* gene family comprises 16 genes in six subfamilies: *GSTA*, *GSTM*, *GSTO*, *GSTP*, *GSTT*, and *GSTZ* (122). Humans show high frequencies for the total deletion of the *GSTM1* or *GSTT1* gene (the so-called null alleles *GSTM1\*0*, *GSTT1\*0*); the incidence of GST-null individuals ranges between 20% and 50%, varying among different ethnic populations.

During the past two decades, dozens of associations have been reported of the NAT2 or NAT1 acetylation phenotypes with toxicity or cancer (56,110); many epidemiological studies suggested associations between *CYP2D6* allelic differences and toxicity or cancer (113). Dozens of publications proposed associations between the *GSTM1\*0* or *GSTT1\*0* allele and either enhanced or diminished risk of cancer or toxicity, depending on the etiologic agent (115). Clearly, without glutathione conjugation, it seems reasonable to expect more drugs or environmental toxicants to be redirected toward more pathways that include highly reactive metabolites. However, as discussed later, recognition has increased that most studies of one or a few SNPs associated with a multiplex phenotype in relatively small cohorts represent statistically underpowered false-positive data (113,124).

## 19.4 ETHNIC DIFFERENCES IN GENE-DRUG INTERACTIONS

Virtually every pharmacogenetic disorder investigated has shown substantial ethnic variability. For example, large ethnic differences exist in frequencies of the rapid-acetylator consensus allele (*NAT2\*4*) vs slow-acetylator

variant alleles (Table 19-2); frequencies of the slow-acetylator allele range worldwide from less than 10% in Japanese populations to more than 90% in some Mediterranean people.

This polymorphism was the first of many that presented a dilemma for the “pure” geneticist: the predominant allele in one ethnic group often is not the predominant allele in another. Which of these alleles should be regarded as the “wild-type?” In the case of the *N*-acetyltransferase polymorphism, the rapid-acetylator allele (inherited as autosomal dominant) was arbitrarily decided to be the “consensus” allele.

Ethnic differences in *CYP2D6* alleles [<http://www.cypalleles.ki.se/>] and many other P450 genes exist. One of the most pharmacogenetically important examples of ethnic variability is *CYP2C19*; among many substrates, this enzyme metabolizes *S*-mephenytoin, omeprazole, diazepam, propranolol, citalopram, indomethacin, proguanil/chloroguanil, imipramine, amitriptyline, mephobarbital, and hexobarbital [<http://medicine.iupui.edu/clinpharm/ddis/table.asp>]. The *CYP2C19* PM patient requires a lower dose of these drugs to achieve efficacy than the *CYP2C19* EM patient. The PM patient is more prone to toxicity than the EM person when both receive the “recommended” commonly prescribed doses of such drugs, especially if the drug has a narrow therapeutic index (Figure 19-3). At least 42 *CYP2C19* mutant alleles have been described [<http://www.cypalleles.ki.se/>], many exhibiting little or no enzyme activity. The incidence of the *CYP2C19\*2A* and *\*2B* alleles (responsible for splicing defects) is 2–5% in Caucasians, yet 20–30% in Asians. This is an excellent example in which the physician must be more careful in prescribing any drug in “the *CYP2C19* repertoire” for an Asian than for a Caucasian patient. Similarly, East Asian drug companies must recognize the importance of the *CYP2C19* polymorphism in their population more so than companies in predominantly non-Asian countries.

Mitochondrial aldehyde dehydrogenase-2 (ALDH2) deficiency is another example of ethnic differences

**TABLE 19-2** Frequency of N-acetylator NAT2 PM Phenotypes in Different Ethnic Populations

Ethnic Population	No. of Studies	Frequency of PM Phenotypes
Japanese	7	0.09
Eskimo	4	0.23
South Pacific Islands	5	0.35
Korean/Chinese	14	0.37
North and South Amerindian	10	0.50
African <sup>a</sup>	19	0.71
Central and West Asian	22	0.74
European	50	0.75
Egyptian	2	0.96

<sup>a</sup>Excluding the Kung Bushman of southern Africa, in which the PM frequency is 0.18. Data modified and condensed from (71).

**TABLE 19-3** Distribution of the ALDH2 Deficiency Phenotype in Different Ethnic Populations

Ethnic Population	Percent Having ALDH2 Deficiency <sup>a</sup>
Japanese	44
Central, East, and Southeast Asian	25–50
South Amerindian	40–45 <sup>b</sup>
North Amerindian	2–5
European, Mideast, and African	<0.1

<sup>a</sup>The mutation in Asians and North American Amerindians appears to be exclusively Glu504Lys, which causes a complete loss of ALDH2 activity in that subunit. The enzyme is encoded by four subunits; if one or more subunits are encoded by the *ALDH2*\*2 allele, then the entire tetramer is inactive. Thus, the *ALDH2*\*1/\*2 heterozygote has  $(1/2)^5 = 1/16$ , or 6.25%, of activity of the *ALDH2*\*1/\*1 subject.

<sup>b</sup>Mutation in South American Amerindians is purportedly different from that in Asians and North Amerindians. Data modified and condensed from (44).

(Table 19-3). The incidence of the *ALDH2* Glu504Lys mutation ranges between 50% and 75% in most Asian populations but is virtually never seen among Africans or Caucasians. A putatively different *ALDH2* allele, causing the same lack of ALDH activity, occurs in South American Amerindians (71), probably due to a founder effect or genetic bottleneck. These data led to speculation that *ALDH2* deficiency arose only in populations traditionally not using ethanol or spices (i.e. Asians have boiled water for at least the past 30 centuries), compared with populations for many centuries using alcohol and spices for enjoyment and preservation of foods.

Why do we see ethnic variability, especially in hPpM genes? Drugs are largely plant metabolites and derivatives thereof; hence, variations in diet of specific ethnic groups for thousands of years have led to important differences in hPpM genes. Examining *NAT2* variants in approximately 15,000 subjects from 128 populations (139) revealed a higher prevalence of the slow-acetylator *NAT2* phenotype in populations practicing farming and herding compared to those relying mostly on hunting and gathering. Perpetuation of mutant alleles resulting in monogenic disorders, as well as in some hPpM traits, can also result from enhanced resistance in the heterozygote to certain infections (114).

How long might it take for the human genome to adapt to dietary selective pressures? By means of genetic drift and natural selection (random mutations, inversions, insertions, deletions, gene duplication, crossing-over events, etc.), new genes will become fixed and passed on to the next generation—if the new configuration confers an ecological advantage to the species. The response of the genome to environmental pressures, over a minimal number of generations, has been described as *molecular drive* (29), *meiotic drive* (157), cryptic genetic variation (CGV) (43), and *decanalization* (42). This response is also likely to influence the processes of drug- or plant-induced efficacy or toxicity.

Whereas mutational changes happen slowly over many dozens of generations, epigenetic changes (i.e. no alteration in DNA sequence) can occur rapidly—in response to severe selective pressures. If the population of a species decreases dramatically so that rare variants are more likely to reproduce, the distribution in that population shifts even more rapidly. Within a population, emergence of individuals resistant to environmental changes has been demonstrated experimentally in various organisms from prokaryotes to insects and vertebrates, but mechanisms involved remain basically obscure. For example, Atlantic tomcod fish developed resistance to polychlorinated biphenyls (PCBs) living in the polluted Hudson River for 50–100 years (50–100 generations); a 6-nucleotide deletion in the *AHR2* gene, resulting in aryl hydrocarbon receptor-2 having poor affinity for planar PCBs, was the basis for the PCB resistance (179). Depending on the organism studied, between nine and 45 generations are usually required (112). For humans, nine to 45 generations require approximately 200 and approximately 1000 years, respectively.

The five major *Homo sapiens sapiens* geographically isolated subgroups diverged from one another between 45,000 and 60,000 years ago (190). Based on animal studies alone, 10,000 years suffice for striking differences in pharmacogenetically relevant mutations to have arisen from selective pressures due to tribal differences in diet or exposure to other environmental signals such as altered climate and altitude. For example, it seems likely that a 10,000-year diet principally of goat meat and milk products on a high desert—compared with that of tropical fruit and fish at the seashore—could cause striking allelic frequency differences in hPpM genes.

## 19.5 PHARMACOGENOMICS

So far, we have described two classes of genes: those contributing to *monogenic* diseases and hPpM traits. The former is a result of mutations in a crucial nonredundant gene, which, when malfunctioning, leads to a serious well-defined disease (e.g. PKU, cystic fibrosis, Gaucher disease, and cystinuria). The latter is a result of mutation in a highly penetrant but noncritical and usually somewhat redundant gene (e.g. *CYP2D6*, *NAT2*, *TPMT*, *CYP2C19*, *SLCO1B1*, *ABCB1*), which, when malfunctioning, can lead to altered plasma or urine drug or metabolite levels or therapeutic failure. Because other redundant enzymes and transporters participate in the same drug pathway, the defect in any one particular hPpM gene is usually only approximately 10–25% accurate in predicting a patient's drug response.

For example, one large retrospective study that correlated thiopurine-related ADRs with the *TPMT* genotype by DNA testing (163) noted that 78% of ADRs were *not* associated with the *TPMT* gene polymorphism, but rather “attributable to factors other than mutations in the *TPMT* gene.” Thus, perhaps the *TPMT* polymorphism

**TABLE 19-4 Partial List of ADRs That Can Occur in Patients Receiving Commonly Prescribed Drugs**

Organ or System	Possible ADRs (Multiplex Phenotypes)
Central nervous system	Headache, fainting, hallucinations, stroke, mood or mental changes (e.g. new or worsening anxiety, nervousness, agitation, confusion, depression, restlessness, sleeplessness, inability to concentrate), memory loss, new or worsening nightmares, seizures, suicidal thoughts or actions, brain damage and psychotic episodes, toxic psychosis, insomnia, anxiety attacks, ataxia, cogwheel rigidity, speech disorder, irritability, panic attacks, postural hypotension
Eyes	Glaucoma, changes in vision, blurred vision, loss of vision, photosensitivity, phototoxicity, dry eyes, periorbital edema, increased tearing, keratitis, cataracts
Gastrointestinal tract	Constipation, severe or persistent diarrhea, gas, nausea, vomiting, severe or persistent stomach pain/cramps, difficulty in swallowing, abdominal cramps, bloody or tarry stools, gastrointestinal disorders, heartburn (dyspepsia), indigestion, ulcers of mouth/esophagus/colon, gingival overgrowth
Heart	Chest pain, shortness of breath, angina, heart failure, heart block, cardiac arrhythmias, sinus tachycardia, palpitations, atrial fibrillation, ventricular fibrillation, postural hypotension
Hematological system	Anemia, unusual bruising or bleeding, excessive bleeding (sometimes fatal), clotting disorders, bone marrow suppression
Immune system	Severe allergic reactions (rash; hives; itching; difficulty breathing; tightness in the chest; swelling of the mouth, face, lips, or tongue; unusual hoarseness), immunosuppression, autoimmune diseases
Inner ear	Tinnitus, dizziness, light headedness, hearing loss
Kidney	Decreased or painful urination, renal insufficiency or failure, hypertension, hypotension
Liver	Symptoms of liver problems (e.g. dark urine, loss of appetite, pale stools, jaundice), chemical hepatitis, liver failure
Musculoskeletal system	Pain, soreness, redness, swelling, weakness, or bruising of a tendon or joint area; muscle pain or weakness; inability to move or bear weight on a joint or tendon area, irreversible tendon damage, spontaneous tendon ruptures, tremor, Ankylosing spondylitis, rhabdomyolysis, bone pain, bone loss, leg cramps
Pancreas	Symptoms similar to diabetes (e.g. high or low blood sugar, dizziness; fainting; fast breathing; flushing; increased thirst, hunger, or urination; increased sweating; vision changes), hypoglycemia, chemical pancreatitis
Peripheral nervous system	Symptoms of nerve problems (e.g. changes in perception of heat or cold, decreased sensation of touch, unusual burning, numbness, tingling, pain, or weakness of the arms, hands, legs, or feet), tremors, irreversible peripheral neuropathy
Reproductive system	Vaginal discharge, irritation, or odor; erectile dysfunction, loss of libido; perpetual erection, painful menstruation
Respiratory tract, lower	Shortness of breath, wheezing, pulmonary edema, pulmonary thrombosis, lower respiratory infection, cough
Respiratory tract, upper	Fever, chills, sore throat, or unusual cough; runny nose; dry nose and throat; stuffy nose and congestion; upper respiratory infection
Skin	Moderate or severe sunburn; red, swollen, blistered, or peeling skin; irreversible skin damage; Stephen-Johnson syndrome; toxic epidermal necrolysis; hives; eczema; edema
"Systemic" (?)	Any type of cancer, facial flushing, obesity, anorexia, decreased levels of sodium, decreased levels of potassium, drug–drug interactions, food–drug interactions, death
DNA changes	DNA damage, mutations, increased risk of cancer

itself might reflect 20–25% of thiopurine-related ADRs. It also should be noted that the red blood cell TPMT enzyme assay is a phenotype reflecting the combination of an unknown number of genotypic variants plus environmental factors (age, illness, renal clearance, recent blood transfusion, etc.). Hence, the TPMT phenotyping assay remains more accurate in predicting drug response than the *TPMT* genotyping assay (116).

The third class of genes represents those contributing to complex (polygenic) diseases (e.g. asthma, schizophrenia, dementia, stroke, obesity, type 2 diabetes, etc.). Understanding this class of genes has changed greatly over the past two decades—due to The Human Genome Project (initiated in October 1990) and the incredible advances in human genomics since then.

Why should consideration of complex diseases concern pharmacogenomics? Because we believe that drug efficacy and ADRs caused by drug toxic levels are similar neither to monogenic diseases nor to hPpM traits; rather, drug efficacy and drug toxicity represent multiplex phenotypes: traits reflecting many genes plus epistatic (gene–gene) effects plus epigenetic effects (gene–environment

### Human complex diseases:

### Drug-induced ADRs:

**FIGURE 19-8** Similarities between complex diseases and drug-induced ADRs, both in genetic origin and phenotypic manifestation.

interactions that accumulate with each passing decade of life). Table 19-4 lists some ADRs in patients who receive commonly used drugs.

These ADRs are analogous to complex diseases (Figure 19-8). Table 19-5 lists examples of FDA-approved prescribed drugs given to a large population, following

**TABLE 19-5** Examples of Prescribed Drugs That Cause ADRs to a Limited Subset of Patients<sup>a</sup>

Name of Drug	Recommended for Treatment of	Number of Patients Treated	Number of Patients Affected	ADR Seen in a Subset of Patients Treated
Januvia (sitagliptin)	Diabetes type 2	Hundreds	88	Acute pancreatitis
Bisphosphonates	Osteoporosis	Unknown	1.93-fold increased risk	Esophageal cancer
Gadolinium-based contrast agents	Medical imaging of kidney disease	Unknown	Unknown	Nephrogenic systemic fibrosis
Meridia (sibutramine)	Obesity	Unknown	Unknown	Heart attacks, stroke
Flibanserin	Depression	Unknown	Unknown	Increased libido in women
Multaq (dronedarone)	Heart disease	Unknown	2	Liver failure
Psychotropic drugs	Schizophrenia, posttraumatic stress disorder, mood disorders, dementia	Unknown	79%, 72% 61%, and 11% increased 10-year risk, respectively	Chronic heart disease
Antidepressants	Depression	5000	Unknown	Acute-angle-closure glaucoma over the age of 66 years
Cladribine	Hairy cell leukemia	Hundreds	1	Progressive multifocal leukoencephalopathy
Pioglitazone	Diabetes type 2	30,173	1.4-fold increased risk	Urinary bladder cancer

<sup>a</sup>This information was taken from the Drug Information Agency daily news over the past 3 years.

which a small subset then develops an ADR appearing to be no different from a complex disease. How does this happen (Figure 19-8)? How does a small-molecular-weight drug, given to a few patients, cause an ADR that resembles a complex disease, whereas the vast majority experience efficacy?

### 19.5.1 How Many Genes Contribute to Each Type of Trait?

A single nonredundant gene is primarily responsible (90–98%) for a monogenic disease (Figure 19-9, *top*). However, additional genes are able to modify the phenotype (onset, severity, etc.), thus contributing the remaining 2–10% to that disorder. As stated above, an hPpM trait (Figure 19-9, *middle*) usually reflects a major gene contributing approximately 10–25% to such traits as plasma or urine drug or metabolite levels or therapeutic failure; however, additional dozens of hPpM genes plus perhaps hundreds of “downstream” genes contribute the remaining 75–90% to the trait.

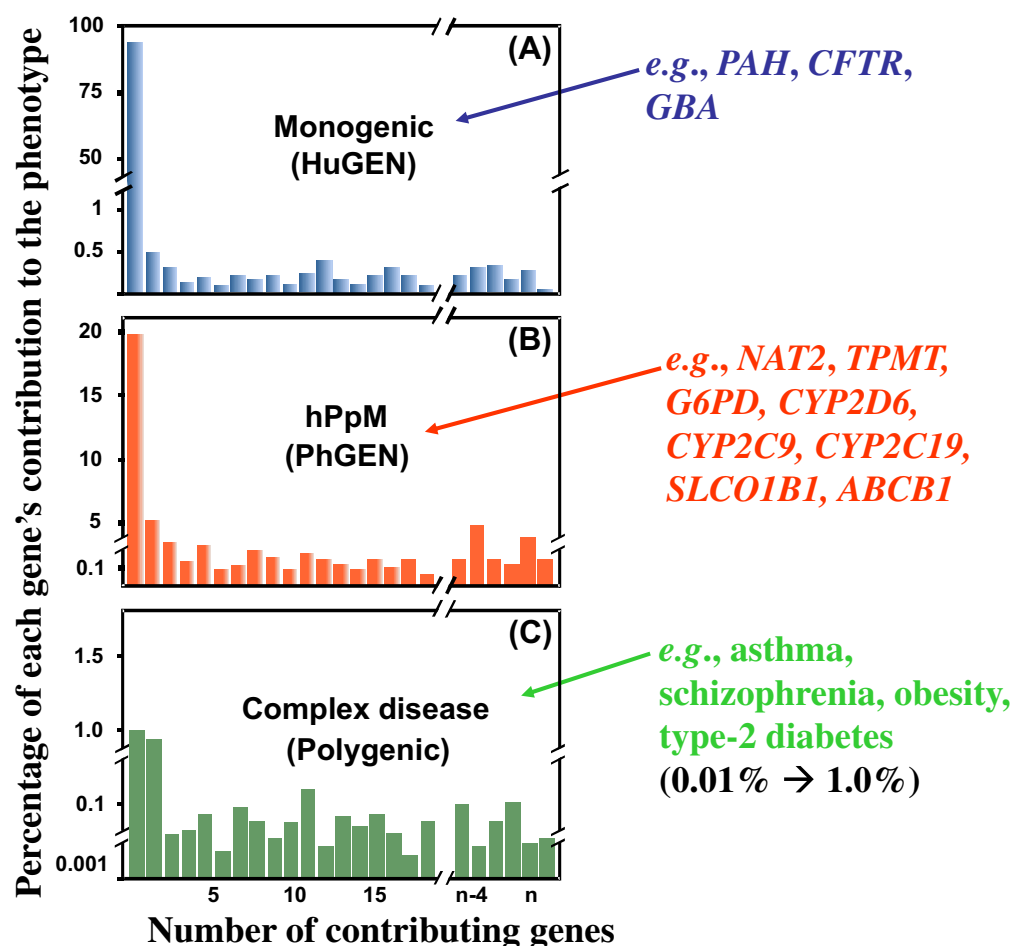

Recent advances in human genomics have now made us realize that hundreds, perhaps thousands, of genes contribute to the *multifactorial trait* that we call *complex diseases* (Figure 19-9, *bottom*). Moreover, it is rare to find any one particular gene contributing any more than 0.001–1.0% (94,162,83); this small amount of individual gene contribution is usually within the “background noise” of most genetic studies—unless large cohorts of 250,000 or 1 million are studied to sufficiently increase statistical power. Indeed, this is why the latest genotype–phenotype association studies are trending toward using larger cohort sizes.

### 19.5.2 Combined 2-Tier PK Plus PD System to Explain Pharmacogenomic Response

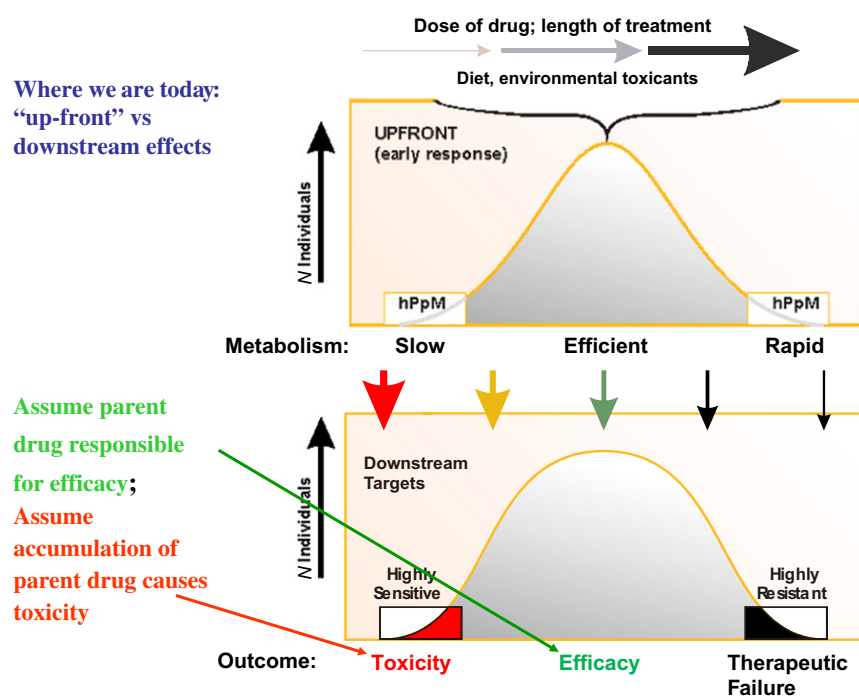

We previously proposed (124) the following 2-tier system (Figure 19-10) that still holds true: (a) front-end differences in hPpM gene polymorphisms are associated with PK processes and (b) downstream genes contributing to the phenotype (drug efficacy as well as ADRs caused by toxic levels of a particular drug) are mostly associated with PD processes. Because of hPpM variability in inheritance, the up-front genes can provide a substantial impact on the PK of any incoming drug or combination of drugs. Because the downstream targets are not usually encoded by hPpM genes, the ultimate outcome (efficacy or toxicity) becomes problematical, i.e. it more closely reflects genes that contribute to virtually any human complex disease.

In clinical pharmacology, most of the upfront gene products are encoded by DME or DRT genes (which have also been termed xenobiotic metabolizing enzyme (XRE) and XRE-related transporter (XRT) genes (113)). In any population, when these genes initially respond to a drug, one can expect slow vs rapid drug metabolism (Figure 19-10). The early-response hPpM genes (Table 19-1) might predict, in part, those individuals at the extreme low and extreme high ends of the spectrum. Responses to the drug by downstream genes will reflect much more of a gradient—from one extreme of toxicity (ADRs), to efficacy, to therapeutic failure (Figure 19-10).

Downstream targets include the class of genes contributing to complex diseases. In the case illustrated, we have assumed that the parent drug is the active form and causes the ADRs, but a similar scenario can be made for a metabolite as the active principle.

**FIGURE 19-9** Percentage of each gene's contributions to the phenotype: (A) monogenic diseases, (B) hPpM traits, and (C) complex diseases. The number of contributing genes (X-axis) will total in the dozens or hundreds. (Modified from Reference (124)).

**FIGURE 19-10** Two-tier system to explain drug toxicity vs efficacy vs therapeutic failure. "Upfront" early responses include the hPpM genes and gene products, which are PK processes. Downstream targets include dozens or hundreds of other genes and gene products, which are PD processes. (Modified from Reference (124)).

Patients having the genetic predisposition for slowest drug metabolism, due to the up-front early-response network, combined with having downstream targets most sensitive to the parent drug, would have the highest risk for accumulation of the drug, leading to *toxicity*. Subjects having predisposition for rapid metabolism, due to the up-front early-response network, combined with having downstream targets most resistant to damage by the specific drug, would clear the drug most rapidly and be at greatest risk for therapeutic failure. Those with intermediate metabolism by the up-front genes would provide the optimum amount of drug to the downstream targets, resulting in the best chance at efficacy. In addition, the dose, drug accumulation, and length of treatment time might all affect this balance (as well as all physiological and environmental factors) and, hence, could ultimately lead to drug toxicity or therapeutic failure, even after the drug had demonstrated efficacy for some period (Figure 19-10). Only a few DNA tests can provide 100% accuracy even for diagnosing monogenic diseases. To date, DNA tests generally cannot provide any more than 10–25% accuracy in predicting an hPpM disorder—in any individual patient.

### 19.5.3 Spin-Offs from the Human Genome Project

We now know that approximately 7% of the human genome has been under purifying selection during the past 100 million years (1,8,83): about 1.5% represents the approximately 21,000 protein-coding genes; regulatory elements controlling gene expression occupy about another 0.5%; and approximately 5% corresponds to functional conserved noncoding elements that produce non-protein-coding RNAs (ncRNAs). The remaining 93% of the genome is likely to have functions; we simply do not know at this time.

Because mouse, rat, and nonhuman primates have approximately the same number of protein-coding genes as humans, clearly we must look elsewhere to explain why all these species differ so much. The diploid genome (two haploid genome sequences from the same individual) was first reported in a Caucasian (89), and now, hundreds of diploid genomes from other ethnic groups have been sequenced. All comparisons between the two haploid genomes in each person have found only about 99.5% nucleotide similarity. These findings are most remarkable in that the nucleotide similarity between a human and a chimpanzee haploid genome is approximately 98.7%! Indeed, *Science* magazine's "2007 Scientific Breakthrough of the Year" (130) was our "newly appreciated recognition of human genetic variability"—i.e. variation in our genome is far greater than most of us could ever have imagined, even just 1 year earlier.

**19.5.3.1 "SNP Fever".** In the mid-1990s, what had been commonly known as "nucleotide substitutions" (by yeast, worm, and fly geneticists for several decades)

was described as SNPs, pronounced "snips". What followed—starting in 1995 and continuing even today—is what we call the "SNP fever." Hundreds of publications sought statistically significant ( $P < 0.05$ ) associations between a few SNPs in one or a few complex disease genes and traits such as hypertension, coronary artery disease, stroke, and even various types of cancer. Not far behind, others sought statistically significant ( $P < 0.05$ ) associations between a few SNPs in one or a few hPpM genes and either drug efficacy or drug-associated toxicity. Almost always, these statistically underpowered, false-positive, uninformative reports could not be corroborated in additional studies (124). Before acceptance of a manuscript, some journals now request confirmation of a genotype–phenotype association in a second ethnic group and/or experimental proof-of-biological-function.

**19.5.3.2 Results from Encyclopedia of DNA Elements.** The Encyclopedia of DNA Elements (ENCODE) Project—comprising many investigators located in at least 80 institutes worldwide—selected 1% of the human genome and examined this in great detail (7). A large variety of parameters was dissected: genes (protein-coding and noncoding exons), promoters, enhancers, repressor/silencer sequences, origin-of-replication and termination sites, conserved sequences, RNA transcripts, transcription-factor-binding sites, methylation sites, DNase I hypersensitivity sites, and chromatin modifications. The human DNA sequence was also compared with those of chimpanzee, mouse, or pufferfish (<http://genome.ucsc.edu/ENCODE>).

Breakthroughs from ENCODE included a greater understanding of: the extensive overlap of gene transcripts and many non-protein-coding regions; complex networks of transcripts (this challenges the concept of "lone transcription units"); many new transcription start sites; an arrangement of "far more complex regulatory sequences and binding of TFs than heretofore imagined"; regulation of genes in *cis* that can be governed by motifs millions of bases away; regulation of genes in *trans* that can be controlled by enhancers even on other chromosomes; interactions among chromatin structure, regulation of transcription, and replication; and finally, 60% of all DNA appears to be under significant evolutionary constraint (7), including the 7% under purifying selection.

These unexpected findings by ENCODE have thrown into disarray previous concepts of "what constitutes a gene" (41). By the end of the twentieth century, "the gene unit" was defined as "a segment of heritable DNA giving rise to a functional product (protein, small peptide, or any of the classes of regulatory RNAs) and including DNA from the 5'-most to the 3'-most regulatory elements." Since 2007, the ENCODE-proposed definition of "the gene unit" has been "a union of genomic sequences coding for a coherent set of potentially overlapping functional products" (7). This definition sidesteps the complexities of regulation and transcription (41).

The complexity revealed by ENCODE (35) has now led to changes in our thinking from “gene expression” as only a local (*cis*-regulated) transcriptional activation to a three-dimensional transcriptional regulatory network that operates in the dimensions of time and space and is cell-type specific. This new appreciation of complexity has now led to thinking in terms of gene expression networks for describing “how the genotype influences the phenotype” of a complex disease. We believe that this same complexity holds true for the many genes involved in drug efficacy and toxicity (ADRs).

**19.5.3.3 GWA Studies.** GWA studies are experiments in which numerous SNPs (usually 1 or 2 million or more, currently across approximately 90% of the genome) are genotyped in large populations. *Multiple locus testing* for statistical associations of each SNP with a phenotype are then performed (137). Phenotypes—including those as diverse as height, skin color, alcohol or caffeine addiction, schizophrenia, neurodegenerative disease, obesity, susceptibility to diabetes or asthma, blood pressure, renal or lung function, bone density, any type of cancer, and fasting glucose or blood lipid levels—can be chosen. GWA studies of drug toxicity, efficacy, or therapeutic failure have also begun to be reported. The power to detect significance (usually  $P < 5 \times 10^{-8}$ ) depends in part on the number of SNPs examined, plus the cohort size (141).

The National Human Genome Research Institute keeps a catalog of all GWA publications in which at least 100,000 SNPs have been studied; associations of genotype with more than 210 phenotypes are currently listed (<http://www.genome.gov/gwastudies/>). At the time of this writing, more than 1300 GWA studies, plus several dozen reviews, have been published. GWA studies have clearly provided numerous putative associations, which by and large can be regarded as “helpful” in understanding complex diseases and hopefully identifying new potential drug targets (46,83). Since 2006, more than 1100 loci affecting more than 210 phenotypes have been associated with common traits and diseases (83).

However, GWA studies have not helped significantly in predicting the risk of common diseases or in predicting drug efficacy or toxicity. The conclusions reached with GWA studies are not that different from the scenario described earlier, i.e. “associations of SNPs in or near one or a few genes with a multiplex phenotype are highly unlikely to be truly statistically significant.”

The biggest problem in taking advantage of all the GWA study information and using it for personalized medicine and individualized drug therapy—is our limited understanding of genomic functional significance. Moreover, we also do not understand the genome’s relationship to epigenetic factors, including drug and other environmental contributions to health and disease. Another problem in interpreting bona fide GWA studies is that causative variants are often located at relatively large distances from the SNP—as much as 2 Mb—and

still contribute to that association (136). This distance can include dozens of genes.

**19.5.3.4 Copy-Number Variants.** Copy-number variants (CNVs) represent segments of DNA—from less than 500 bp to more than 2 Mb—that can be duplicated in one’s genome up to 48 times or deleted. In a map constructed from 185 human genomes (108), more than 28,000 CNVs were identified; thus, several hundred CNVs generally occur in one genome. CNVs comprise as much as 15% (approximately 450 Mb) of our genome, and CNV patterns can vary from one cell to the next in the same tissue, i.e. mosaicism (91). In twin studies, some CNVs were even found to differ between copairs of identical twins (13,98).

Significant effects of CNVs on complex disease, drug efficacy, and ADRs remain unclear. Some studies have suggested that CNVs are associated with certain complex diseases including cancer and neurological disorders, whereas others are not. However, if CNVs encompass hPpM genes, they are highly likely to influence drug or metabolite levels in plasma or urine and/or the phenotype of therapeutic failure (53).

**19.5.3.5 Examples of Pharmacogenomics GWA Studies.** Recent advances in pharmacogenomics and drugs have been made through the use of candidate gene and genome-wide studies (Table 19-6). At present, one highly popular association is the combination of mutations in the *CYP2C9*, *VKORC1*, and *CYP4F2* genes, which might “contribute as much as 35–50% of the patient’s total variation” in the optimal dose of warfarin anticoagulation (101). This level of “certainty” in the individual patient, however, is insufficiently high for the physician to treat the patient with confidence.

Perhaps the two most striking influences seen clinically in drug-treated patients, because of major changes in plasma drug levels, are the effects of (a) poor- vs rapid-metabolizer-*CYP2C19* phenotypes and outcome of clopidogrel treatment and (b) ultrarapid metabolizer *CYP2D6* phenotypes following codeine therapy (68).

In a GWA study of “habitual caffeine intake,” more than 47,000 individuals of European descent within the United States were compared by meta-analysis adjusted for age, sex, and smoking history (18); two SNPs achieved genome-wide significance—one near the *AHR* gene and the other near the *CYP1A2* gene. The study makes sense functionally, because *CYP1A2* metabolizes caffeine and *AHR* regulates *CYP1A2* expression. However, this observation does not contradict our main message: poor predictability of genetic variants for a multiplex phenotype such as “caffeine addiction.” This study represents an issue of effect size (predictability and clinical utility) instead of just the *P*-value (analytical validity); one can establish the association with highly significant *P*-values by meta-analysis of almost 50,000 samples, but the effect sizes remain extremely low (<1% contribution to the trait). Therefore, this finding has no clinical utility whatsoever. The result, however,

does increase our knowledge about caffeine intake and metabolism.

A similar GWA study of metabolic traits in nearly 2000 subjects from two cohorts found an SNP near the *NAT2* gene to be highly significantly associated with coronary artery disease and response to drug toxicity (151). In a meta-analysis of 23 studies evaluating *GSTM1* and 19 studies evaluating *GSTT1* (39), a *GSTM1*–*GSTT1* interaction in patients having the dual null genotype was strongly associated with increased risk of uterine cervical cancer. Meta-analysis of two populations totaling approximately 40,000 subjects detected a strong association between an SNP near the *ALDH2* gene and elevated blood pressure (75). However, the effect size is far too small in each of these large-population studies ever to consider testing individual patients.

In each of the pharmacogenomics examples in Table 19-6, some patients with the mutation were not associated with the phenotype and other patients without the mutation were associated with the phenotype. As originally described by Fisher (38), *statistical interaction* is a *population-level concept*, whereas for the *individual* (patient), we need to understand the *biological interaction* or *function*. In other words, when testing for statistical interaction, the resulting model can be far more complex than is justified by the power that the sample design permits (172).

This problem also underscores the complexity of calculating the “cost–benefit” ratio: after the patient pays for a test and if the physician remains unconvinced by the result, what benefit is this test? Most importantly, this is why the use of genotyping to make informed clinical decisions about individualized drug therapy is not widely practiced. This “degree of uncertainty” reinforces our contention as to the difficulty in achieving any DNA test acceptable to the physician for *predicting* risk of a multiplex phenotype, such as complex diseases, drug efficacy, or ADRs.

### 19.5.4 The Dilemma: “Missing Heritability” in Multiplex Phenotypes

Concerning GWA studies, what has changed scientifically in the last few years is the accumulating confusion concerning GWA studies and their ability to identify unequivocally important genes for complex diseases in human populations. In study after study, applying GWA to every common disease, the results have been remarkably consistent: only genes having very minor effects have been uncovered (2,26,100). In other words, are causative alleles common or rare? Synthetic associations created by rare variants have not explained most GWA study data (3,142,181). The genetic variation—confidently expected by medical geneticists initially to explain common diseases—cannot be found. Medical geneticists do not dispute the GWA results themselves but are now assuming that genes predisposing to common diseases

must somehow have been missed by the GWA methodology. There is a big problem, however, in that geneticists have been unable to agree upon where this “dark matter of DNA” might be hiding.

In addition, we have seen large GWA studies of particular multiplex phenotypes in which the same ethnic cohort has been analyzed by several laboratories—with distinctly different results (67,125). In some instances (Table 19-7), a locus is identified by all three laboratories; in other cases, only two of the three laboratories found the highly significant locus; and on still other occasions, only one of the three laboratory found a highly

significant gene or locus. It has been posited (42) that all three publications might, in fact, be correct and that these data might be explainable on the basis of epigenetic effects, to be discussed later.

Recently it has become possible to determine the amount of contribution by all identified genes toward any multiplex phenotype—addressing the question as to how much of the heritability can be attributed to each locus identified by GWA studies. A list of percent contribution of SNPs identified by GWA studies contributing to several traits is summarized in Table 19-8. The recent concern about GWA studies (57) is the fact that the total contribution of all genes “identified as being significantly associated (having *P*-values between  $5 \times 10^{-8}$  and more than  $10^{-250}$ ) with a *multifactorial trait*”—is surprisingly small (45,83).

Although 20 loci were initially highly associated with height (49,87,167,173), all variants combined could not explain even 3% of the population variation in height. In a cohort of more than 183,000 subjects (84), at least 180 loci could explain only approximately 10% heritability of the phenotypic variation in height. In fact, in a study of 500,000 unrelated individuals, although 100% of those at the effect size (detected so far with existing power) might be found, this would still amount to no more than approximately 30% of all height heritability; one inference is that “the other 70% would participate in even smaller effects.” To fit the observed distribution of variants explained by genetic markers from GWA studies, real-disease models (e.g. lipid profiles, diabetes type 2, and Crohn disease) were examined (147). Estimates

**TABLE 19-8** Several GWA Studies Showing Contribution of SNPs to That Trait<sup>a</sup>

Phenotype	Number of Loci Found	Proportion of Heritability Explained (%)
Diabetes type 1	41	~60
Fetal hemoglobin levels	3	~50
Macular degeneration	3	~50
Diabetes type 2	39	20–25
Crohn disease	71	20–25
LDL and HDL levels	95	20–25
Height	180	~12
Body mass index	At least 35	6–11
Prolonged QT interval	14	~5.0–6.5

<sup>a</sup>Taken, in part, from (83).

indicate that probably hundreds to nearly a thousand variants underlie these multiplex phenotypes.

Currently, a consensus explanation for this puzzle of “missing heritability” in complex diseases has not yet emerged. Genetic studies might fail because (1) interrogative methods cannot identify the causal genetics (i.e. “genome-wide” measurements with SNP chips currently cover no more than 90% of the entire genome), (2) phenotyping is incorrect, or (3) the trait is not heritable (e.g. *de novo* mutation not found in either parent) (26).

In conclusion, there appears to be a serious “missing heritability” problem that demands attention be directed to other sources of variance. This unexplained heritability could be partly due to gene–environment interactions or more complex pathways involving multiple genes, gene–gene interactions (epistasis), and exposures (159).

It should be acknowledged that some (185) still “have no reason to believe that any heritability is missing”; some propose that consistent effects of epigenetic variants, gene–environment interactions, and nonadditive traits (of combinations of variants) be excluded from consideration, because these factors are taken into account when defining “heritable genetic variance.” Consistent with this argument, a comparison of 29 whole genome sequences (193) suggested that “the rare variants are significantly more likely to be functional than the more common variants.”

### 19.5.5 Increasing Appreciation of the Epigenome

Epigenetics and the epigenome are among many the reasons for explaining the above-discussed dilemma of missing heritability. Examples of epigenetic effects include *DNA methylation* patterns, covalent *modifications of histones*, *chromatin remodeling*, *RNA interference* (RNAi) processes, and *decanalization*. Some of these categories are currently better understood than others. Epigenetics might provide a new framework for our search of etiological factors contributing to complex diseases, drug efficacy, and ADRs.

We are certain that there will also be “genetic differences” in epigenetic response: monozygotic co-twins are expected to exhibit more similarities in epigenetics than dizygotic co-twins. In support of this, on comparing DNA methylation in co-pairs of monozygotic with that in copairs of dizygotic twins (73), there was significantly less epigenetic variability in buccal cells from monozygotic than dizygotic copairs of twins ( $P = 1.2 \times 10^{-294}$ ).

During the past decade, there has been an explosion in appreciation of epigenetics. Some epigenetic variants can be inherited by offspring (or the offspring’s offspring)—indicating the existence of a *transgenerational* mechanism (23) for biological heredity not based on DNA sequence. For example, because of the Dutch Famine of 1945, neurodevelopmental disorders increased in grandchildren whose grandparents were exposed prenatally (153). Famine in a small Swedish village, at the time a male enters puberty, sends an unknown message to his grandson, resulting in *less risk* of diabetes type 2; famine in the same population, when a female’s oocytes are forming during the third trimester in utero, *increases the risk* of obesity and diabetes type 2 in that baby’s granddaughter (129). Cigarette smoking during pregnancy by a grandmother increases the risk of asthma in the granddaughter by four-fold (90). Germ cells can carry epigenetic effects from the grandmother’s diet (17). Individuals whose grandparents suffered malnutrition in utero during the 1959–1961 Chinese famine have increased risk of schizophrenia (183); however, another analysis of these same data suggests that this result might reflect population stratification (148). Even chronic stress in the pregnant mother (70) or dietary effects in the father’s sperm (126) are believed to be sufficient to induce changes in the *epigenetic landscape* of the developing embryo and fetus in utero.

It is extremely likely that epigenetic changes are involved in various complex diseases including cancer and asthma (37). We believe that the epigenome is also likely to play a role in drug efficacy and ADR phenotypes. Epigenetic effects increase with each passing decade of life, because of constant bombardment of environmental stimuli (which include drugs—as well as diet and chemical or metal toxicants). Within the next several years, there should be many more examples of epigenetic-mediated effects on gene–drug interactions.

**19.5.5.1 DNA Methylation.** Genome-wide DNA methylation occurs as a function of time in a highly specific cell-type manner. DNA hypermethylation is known to reflect environmental impact, as a function of each increasing decade of life. Promoter hypermethylation usually results in turning genes “off,” whereas promoter hypomethylation usually turns genes “on.” Vast differences exist between individual DNA methylation loci and are sometimes under genetic control, as well as related to age and gender (10). DNA methylation can modify the regulation of hPpM genes—thus changing drug or metabolite profiles in blood or urine or altering the degree of therapeutic failure.

Individuals exposed in utero during the Dutch famine of 1945, when examined six decades later, showed less DNA methylation of the imprinted *IGF2* gene, compared with their unexposed same-sex siblings (55); this study demonstrates that early-life environmental conditions can cause transgenerational epigenetic changes in humans that persist throughout life of that individual. Genome-wide analysis of DNA methylation in peripheral blood was compared among current smokers, former smokers, and those who had never smoked (11); significant differences were found between smokers and the other two groups. Looking at DNA methylation changes in a specific gene, or even a group of genes, faces the same difficulties (*vide supra*) as looking at SNPs in one or a few genes, i.e. multiplex phenotypes might reflect hundreds of genome-wide DNA methylation changes, each contributing 0.001–1.0% to variability in the trait.

**19.5.5.2 RNA Interference : MicroRNAs.** The human genome encodes more than 2000 MicroRNAs (miRNAs) in approximately 100 evolutionarily conserved families. The miRNAs are 20- to 25-nucleotide-long ncRNAs that regulate gene expression posttranscriptionally by mediating translational repression or promoting degradation of their target mRNAs (15,79,169). Each typical conserved miRNA targets, on an average, approximately 200 mRNAs. Clearly, genetic variation in one’s miRNA profile can be pivotal not only in hPpM disorders but also in monogenic diseases and multiplex phenotypes, i.e. complex diseases, drug efficacy, and ADRs.

**19.5.5.3 Chromatin Remodeling.** Transcription in mammals is regulated by TFs that associate with the genome in a cell-type-, temporal-, spatial-, and condition-specific manner. Chromatin organization forms part of the basis for this cell-type specificity by allowing or denying TF access to regulatory DNA regions. The basic units of chromatin structure are the nucleosomes. Heritable chromatin status and TF binding can differ because of genetic variation, which in turn may underlie phenotypic variation in humans. This field has just begun to be appreciated, but there are implications for effects on all the traits mentioned above.

**19.5.5.4 Histone Modifications.** Histones form the protein core around which eukaryotic genomic DNA is wrapped in chromatin. The structure and the transcriptional state of chromatin are closely associated with histone posttranslational modifications, which can affect gene expression. The highly heterogeneous nature of histone modifications in the intact cell or animal poses a daunting challenge for the future. Again, we can expect to find histone modifications that will affect all the traits mentioned above.

**19.5.5.5 Decanalization (“Cryptic Genetic Variation”; “Molecular Drive”).** *Canalization* pertains to “the evolution of robustness to genetic or environmental perturbation in populations.” Environmental perturbation includes the effects of diet, stress, or drug usage; because canalization can also be inherited transgenerationally,

there is likely to be an interrelationship with DNA methylation and other epigenetic processes. Most of these (virtually unknown) canalization mechanisms have been delineated in the fruit fly, but we predict that this process in humans will affect some or all of the traits mentioned above. In canalized populations, most individuals tend to cluster around the robust optimal phenotype. A decanalized individual would be significantly outside this robust optimum and, hence, more susceptible to an altered condition—including certain complex diseases, ADRs, or degree of drug efficacy.

Consider the rapid “telescoping” of the human genome during the past few hundred years, compared with the previous 5–6 million years since hominids diverged from apes. For 5 million years, evolution was very gradual and able to accommodate comfortably to environmental or genetic alterations. In contrast, during the past 6000 years, humans have gone from hunter-gatherer, to farmer, to villager, to living in towns and polluted cities. Dramatic cultural changes in the past few centuries (striking dietary shifts, tobacco smoking, air pollution, altered pathogen exposures, psychological stress, and consuming prescribed vs over-the-counter vs recreational drugs) have dramatically pushed physiology away from the evolved robust mechanisms normally preventing disease. Thus, our genome has undergone tremendous “telescoping,” on comparing the past one to two dozen generations with the previous 3000 generations (42).

If we consider these striking environmental and cultural perturbations during recent generations, this might lead to the uncovering of CGV (140) as a major source of complex disease susceptibility. Processes of drug efficacy and risk of ADRs might similarly reflect decanalization. For example, the increases that we see in rates of obesity and autism spectrum disorder, as well as psychotropic drug-induced obesity—during these past few decades in western societies—might mirror decanalization that has occurred very recently. Moreover, the “missing heritability” from GWA studies (*vide supra*) might well correspond, at least in part, to decanalization.

## 19.5.6 Beyond DNA Sequence Assays

**19.5.6.1 Transcriptomics.** Transcriptomics (61,106) and laser-microdissection transcriptomics (14) refer to the studies of gene transcripts—generally analyzed by cDNA expression microarrays. These arrays measure the amount of steady-state mRNA levels in the tissue being studied, which of course can sometimes differ substantially from the amount of functional protein in that tissue. Such cDNA expression studies have led to a number of exciting breakthroughs in basic science, as well as in cancer biology, in which prognosis and treatment can sometimes be more accurately directed by observing an expression profile of a tumor (6).

**19.5.6.2 Proteomics.** Proteomics is the study of all proteins encoded by the genome; protein or metabolite

profiles can be studied in urine, tissues, or even single cells (138). Although an average of 3.0 proteins per gene has been estimated, others suggest that the true number of proteins per gene might be much higher. In theory, protein profiles from various sources should represent the outcome of all genetic plus epigenetic effects; from this standpoint, it might be more comprehensive than transcriptomics.

Why is transcriptomics or proteomics unlikely to play a major role in individualized drug therapy? The answer is related to the major limitation of microarray expression in patients receiving drugs: i.e. easy access of the appropriate source of sampling—blood, excreta (urine, saliva, sweat, breast milk, ejaculate, menses, feces), or tissue in which relevant cDNAs exist (dissected tumor, tissue biopsies, placenta, foreskin). It would not be ethical or reasonable, for example, to attempt to predict individual psychotropic drug response outcomes from brain biopsies in healthy patients.

It is conceivable that proteomics in the future might identify certain protein profiles—similar to the ways in which metabolomics can identify certain metabolite profiles. At present, it is not known whether this will become useful in predicting complex diseases, drug efficacy, or risk of ADRs.

**19.5.6.3 Metabolomics.** The “metabolome” represents an integrated response, in real time, to all endogenous processes plus all exogenous stimuli (drugs, chemical exposures, occupation, lifestyle, nutrition, disease state, age, and gender). The metabolome should reflect all genetic plus epigenetic variability. Metabolomics therefore might provide an exquisitely sensitive means to follow an individual’s total phenotype—as a function of age, nutrition, course of disease, or therapy. Accordingly, in principle, this technique offers great promise to individualized drug therapy and personalized medicine but will also be subject to some of the pitfalls identified above for pharmacogenomics.

Metabolites measured include not only those from drugs but also thousands of small-molecular-weight compounds that exist in every metabolic pathway in our bodies. The patient’s intestinal flora interacts extensively with the host, resulting in metabolic exchange in the gastrointestinal tract and shared metabolism of substrates—which can be detected by metabolomic analysis (16).

This method of analysis is so sensitive that one can detect diurnal rhythm, menstrual cycle, and foodstuff recently consumed. Accordingly, metabolomic analyses will be required to pay particular attention to the time of day, time of month for menstruating females, recent dietary intake, and recent exercise history, as well as exposures to perfume, hairspray, cosmetics, cigarette smoke, occupational chemicals, pollen, urban vs rural air, and perhaps new furniture and rugs.

Urinary metabolite profiles of the individual patient are expected to reflect, at that particular moment in

time, the combination of all genetic and epigenetic influences. Metabolomics might be regarded as being similar to a “liver profile” test in clinical pathology, except that metabolomics includes measurement of metabolites present at much lower concentrations and, accordingly, provides several orders of magnitude greater sensitivity (femtomolar to attomolar range). Even though metabolite profiling can be performed only on available samples, such as blood, urine or other excreta, dissected tumor, or biopsy tissues, this method still holds promise of clinical success and might be regarded as an extension of the present practice of clinical pharmacology (123,136,138).

Clinical pharmacologists primarily have been using blood or urine to follow therapeutic responses for the past 60 years. This new form of metabolite profiling would resemble what clinical pharmacology has been doing previously, but would be several orders of magnitude more sensitive in detecting drug efficacy or risk of ADRs, perhaps long before these become clinically overt. Ultimately, it is anticipated that the combination of metabolomics, proteomics, and transcriptomics will complement genomics and epigenomics in revolutionizing individualized drug therapy.

## 19.6 CONCLUSIONS

1. The human genome is incredibly complex, far more than most of us could ever have imagined.
2. Phenotyping assays therefore remain superior to (DNA) genotyping assays in assessing most pharmacogenetic and pharmacogenomic disorders.
3. Statistical interaction is a population-level concept, whereas for the individual, we need to understand biological interaction or function; therefore, DNA variants showing statistical significance in a large cohort often have too small an effect size to predict in, or provide benefit to, the individual patient.
4. We categorize genes into three types—those associated with monogenic traits, hPpM disorders, and complex diseases.
5. The hPpM genes are principally responsible for changes in urine or plasma drug or metabolite levels, as well as therapeutic failure.
6. Drug efficacy and ADRs usually represent multifactorial traits that are conceptually not different from complex diseases.
7. One gene generally contributes 90–98% to a monogenic disease, whereas one hPpM gene might contribute 10–25% to an hPpM trait; in contrast, one gene might contribute 0.001–1.0% to multiplex phenotypes such as complex diseases, drug efficacy, or risk of ADRs.
8. GWA studies have been extremely useful in identifying genes participating in multifactorial traits; these might lead to the discovery of novel drug targets.

9. After more than 1300 GWA publications, we realize that the contribution of the total number of genes associated with any multiplex phenotype is between 5% and perhaps 60%. The remaining 40–95% is referred to as “missing heritability.”
10. It is likely that epigenetics is the main contributor to this missing heritability.
11. Epigenetics includes DNA methylation, RNAi processes, histone modifications, chromatin remodeling, and decanalization (also called CGV).
12. Urinary metabolite profiles in the individual patient are expected to reflect, at a particular moment, the combination of all genetic and epigenetic influences.
13. Transcriptomics, proteomics, and metabolomics might complement genomic (DNA sequence) assays in achieving improved success in personalized medicine, a large subset of which is individualized drug therapy.
14. Given all the complexity of the human genome, it is now easy to realize how difficult it would ever be to predict a common disease (*personalized medicine*) or to predict in advance “which drug and dose to give” (*individualized drug therapy*) to an individual patient.

### Biographies

After college at Wesleyan University; Middletown, CT, Daniel W Nebert earned his combined MS degree (Biochemistry) and MD degree at the University Oregon Medical School in Portland. He then did his internship and residency in clinical pediatrics at the UCLA Medical Center (Los Angeles), before spending more than 20 years at the National Institute of Child Health & Human Development (NICHD), National Institutes of Health (NIH, Bethesda), where he was Chief of the Lab of Developmental Pharmacology (1975–1989). Joining the University Cincinnati Medical Center in December 1989, he became Professor in the Department of Environmental Health, with a joint appointment since 1991 as Professor of Pediatrics and Molecular & Developmental Biology, Division of Human Genetics. Nebert is board qualified in both Pediatrics and Human Genetics and has maintained a medical license in the states of California and Ohio. He has received many national and international awards including the coveted Bernard B. Brodie Award on Drug Metabolism given by the American Society of Pharmacology and Experimental Therapeutics (1986) and the Society of Toxicology's "Distinguished Lifetime Toxicology Scholar" Award (2005). He is currently the author and coauthor of more than 600 basic and clinical science publications, invited reviews, and book chapters.

Elliot S Vesell, MD, ScD, received a BA from Harvard College, magna cum laude, Phi Beta Kappa (1955); received his MD from Harvard Medical School, magna cum laude (1959); and interned at Massachusetts General Hospital (1959–1960). Dr Vesell was a Research Associate and Assistant Physician at Rockefeller University (1960–1962), and Assistant Resident in Medicine at Harvard's Peter Bent Brigham Hospital in Boston, MA (1962–1963). He was a Clinical Associate at NIH's NIAMD in Bethesda, MD (1963–1965), and then Head, Section on Pharmacogenetics, NHLI, NIH (1965–1968). In 1968, Dr Vesell was named the Founding Chair and Professor of Pharmacology of The Penn State University's new medical school, at the Penn State College of Medicine and Milton S. Hershey Medical Center, in Hershey, PA, his tenure as Chair lasted until 2000. He also served as Assistant Dean of Graduate Education from 1973 to 1995. Dr Vesell was selected in 1981 as Evan Pugh Professor, Penn State's highest honor bestowed upon a faculty member. He remains as Evan Pugh Professor Emeritus. Dr Vesell has received four national awards in clinical pharmacology and two honorary doctorates from major universities. He has published 335 peer-reviewed articles in the medical literature.

## Genetic Evaluation for Common Diseases of Adulthood

Maren T Scheuner and Shannon Rhodes

### 20.1 BACKGROUND

Common diseases such as coronary heart disease (CHD), stroke, cancer, and diabetes are high-prevalence diseases that have considerable impact on public health. Common diseases are typically chronic conditions that develop over decades, usually occurring in adulthood because of genetic and environmental risk factors, including exposures, infectious agents, and cultural and behavioral factors such as diet and exercise (i.e. multifactorial etiology) (Figure 20-1). Rarely, a common chronic disease of adulthood can occur as the manifestation of a Mendelian disorder, and *variable expressivity* and *reduced penetrance* are typical (1). *Genetic heterogeneity* is also characteristic of genes contributing to Mendelian forms of common diseases. For example, there are at least four genes known to cause Lynch syndrome, the most common form of hereditary colon cancer (2) and 12 genes are known that cause hereditary hypertrophic cardiomyopathy (3). *Pleiotropic effects* of genotypes contributing to common diseases can exist and must be considered when offering genetic testing. For example, methylenetetrahydrofolate reductase (*MTHFR*) gene polymorphisms predispose to cardiovascular disease (4), neural tube defects (5), and colorectal cancer (6), and the apolipoprotein E genotypes contribute to serum cholesterol differences in the population and have been associated with cardiovascular disease (7) and Alzheimer disease (8).

Genetic tests are increasingly available for both Mendelian and multifactorial forms of common diseases. Genetic test results have the potential to impact health outcomes by improving our ability to diagnosis, treat, and prevent common diseases. To date, *multiplex testing* for common diseases has limited proven utility (9) and family history remains the best strategy for assessing genetic risk for these disorders (10). Family history is also key to identifying individuals at risk for Mendelian forms of common diseases (1).

Early disease detection and prevention are possible because of the chronic nature of common diseases, whether inheritance is Mendelian or multifactorial. Outcomes relating to genetic evaluation for common diseases can be characterized as psychological, cognitive, behavioral, or clinical (11). Results of genetic tests can be used to inform the shared clinical decision-making process between health care providers and patients and reproductive and personal decisions made by patients, such as decisions about career, finances, and marriage.

#### 20.1.1 Psychological and Cognitive Outcomes

Generally, psychological and cognitive outcomes related to genetic counseling and testing for common diseases are positive. Many studies have shown that genetic counseling for inherited susceptibility to breast cancer among women affected with breast cancer, and those at risk because of family history, did not increase psychological distress and resulted in some improvements in decreasing worry, anxiety, and depression (12,13). Studies assessing psychological or affective outcomes before and after genetic counseling in patients at risk for hereditary colon cancer reported improvements in satisfaction, knowledge, and reductions in worry (14,15). A randomized controlled trial on the disclosure of apolipoprotein E (ApoE) genotype to participants with a parent diagnosed with Alzheimer's disease found no difference in depression, anxiety, or distress in those who received genotype information compared to those who did not (16). Generally, even 1 year after ApoE genotype disclosure, participants in the study considered that the benefits of genetic testing outweighed the risks (17). A randomized controlled trial in adult non-diabetic offspring of diabetic parents reported that education and personalized prevention recommendations

**FIGURE 20-1** Both genetic and environmental factors contribute to the development of common diseases such as CHD, diabetes and cancers. Disease is least likely for individuals who have genotypes that are protective and who have favorable environmental exposures. Conversely, disease is most likely for individuals who have predisposing genotypes and unfavorable environmental risk factors. In industrialized cultures, unfavorable environmental factors such as inactivity, excess calories, processed foods, tobacco, alcohol, radiation and pollution are common with nearly everyone encountering them. Therefore, individuals who develop common chronic diseases, especially at young ages, are generally those who have the greatest genetic predisposition.

increased the accuracy of risk perception for diabetes without increasing worry (18).

### 20.1.2 Behavioral and Clinical Outcomes

A survey of family practice physicians found that they expect their patients to be more likely to get screened for cancer and make lifestyle and behavioral changes if genetic testing identified them as being at increased risk (19). However, a systematic review of 11 studies assessing behavioral responses to genetic risk information among individuals at risk for cancer found mixed results, with some studies showing no change in behavioral outcomes, whereas others reporting increased participation in cancer screening (20). A few studies have documented lifestyle changes after receiving genetic test results. Reduction in smoking was observed (although results were short lived) after receiving genetic test results that revealed information about cancer susceptibility related to smoking, (21,22) and a significant increase in dietary supplement use was observed in ApoE4 allele carriers at risk for Alzheimer's disease compared to noncarriers (23) despite the absence of scientific support for dietary supplements in preventing Alzheimer's disease (24).

Clinical outcomes, such as reduced incidence of disease after a recommended intervention, are less well studied. A study that assessed clinical outcomes in 251 women with *BRCA1* or *BRCA2* mutations reported that after counseling 15% and 50% underwent risk-reducing surgery for breast cancer and ovarian cancer, respectively, and four early-stage cancers were identified at surgery. Among women who did not undergo prophylactic surgery, recommended cancer screening increased (25).

## 20.2 THE PROCESS OF GENETIC EVALUATION FOR COMMON DISEASES

Clinical genetic evaluation for common disease should be considered for individuals with a strong familial risk or when a Mendelian disorder is suspected. Genetic evaluation is composed of several components including (1) genetic risk assessment and diagnosis through clinical assessment, family history assessment, and genetic testing; (2) appropriate recommendations for management and prevention given a genetic risk or diagnosis; and (3) genetic counseling and education.

### 20.2.1 Clinical Assessment

Assessment of signs and symptoms of the disease of concern should be performed to more accurately assess risk for the patient. For example, when evaluating a genetic risk for heart disease, review of systems should include questions regarding angina, shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, pedal edema, palpitations, claudication, and exercise tolerance. In the case of risk assessment for colorectal cancer, questions should be asked regarding frequency of bowel movements, caliber and color of the stool, and presence of blood in the bowel movement. If symptoms are present, follow-up confirmatory testing should be recommended, for example, stress testing or echocardiogram to evaluate cardiovascular symptoms or colonoscopy to assess change in bowel habits or blood in the stool.

Physical examination should be performed to identify signs of the disease of concern as well as characteristic manifestations of Mendelian forms of a disease. For example, an evaluation for cardiovascular risk should include auscultation of the heart, lungs, and major vessels in the neck, abdomen, and groin and palpation of the aorta and distal pulses. Any abnormality can be followed up with additional studies, such as ultrasound. Blood pressure in the upper and lower extremities can identify hypertension, and these measurements can be used to calculate the ankle-brachial blood pressure index (ABI). Values  $<0.9$  are correlated with atherosclerosis. Weight and height should be obtained, and body mass index calculated to identify overweight and obese patients; follow-up measurements can help monitor diet and exercise interventions. Waist circumference should be obtained, as increased values are associated with the metabolic syndrome, a common cause of cardiovascular disease (26). Evaluation of possible lipid disorders should include examination of the eyes, assessing corneal arcus and lipemia retinalis, and examination of the skin for xanthelasma and tendinous xanthomas. Physical signs of Mendelian disorders that feature cardiovascular disease should be assessed, such as dolichostenomelia and arachnodactyly associated with Marfan's syndrome, abnormal scarring and translucent skin associated with Ehlers-Danlos syndrome type IV,

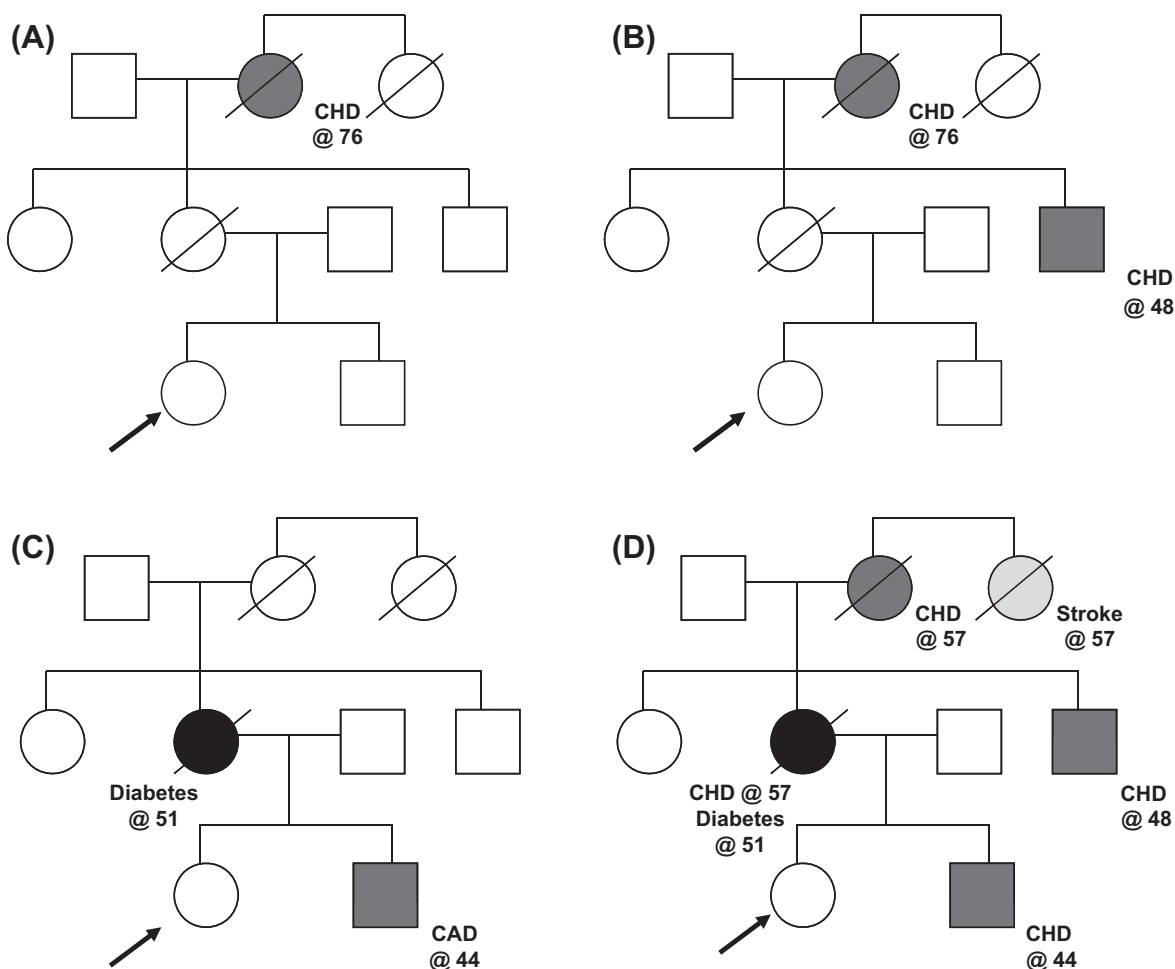

popular skin lesions and plaques in flexural creases and angioid streaks on the retina associated with pseudo-xanthoma elasticum, and angiokeratomas (vascular cutaneous lesions) and corneal and lenticular opacities associated with Fabry disease.

### 20.2.2 Family History Assessment

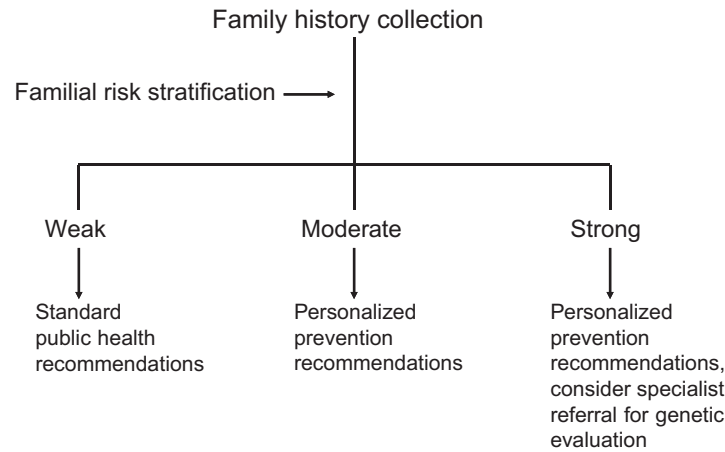

Currently, family history collection and interpretation is the most practical strategy for identifying individuals with a genetic susceptibility to many common chronic diseases (10,27). Family history represents complex interactions of genetic and nongenetic factors (e.g. exposures, diet, and behaviors) shared by family members. For many common diseases, a positive family history is quantitatively significant, with relative risks ranging from two to five times those of the general population, and this risk generally increases with an increasing number of affected relatives and earlier ages of disease onset (28–36). Family history characteristics that suggest

a possible Mendelian disorder include early age at diagnosis, two or more closely related relatives affected by a disease or a related condition, a single family member with two or more related diagnoses, multifocal or bilateral disease, and occurrence of disease in the less-often-affected sex (e.g. male breast cancer). By recognizing the magnitude of risk associated with these familial characteristics and patterns of disease consistent with known Mendelian disorders, stratification into different familial risk groups (e.g. weak, moderate, and strong) is possible (Figure 20-2), which can guide risk-specific recommendations for management and prevention (Figure 20-3). Referral for genetic evaluation by a geneticist or other specialist is appropriate for individuals with strong familial risk or a suspected Mendelian disorder.

An important step in family history assessment for common chronic diseases is pedigree analysis, which begins with the creation of the pedigree structure. This usually includes all first- and second-degree relatives and spans three to four generations. Demographic

**FIGURE 20-2** Each of the pedigrees are “positive” for a family history of CHD. However, the level of familial risk is different for each. In pedigree A, the consultand reports a maternal grandmother with CHD at age 76; her family history is a weak risk factor. In pedigree B, there are two second-degree maternal relatives affected with CHD; one diagnosed at an early age (48) and the other at a later age. This family history is more significant, but is likely only a moderate risk factor. Pedigree C is more concerning and consistent with a strong familial risk since a first-degree relative is affected with CHD at a young age. The report of diabetes in a first-degree relative in pedigree C may be related and is suggestive of the metabolic syndrome. The highest familial risk is seen with Pedigree D, which has three generations of early-onset CHD.

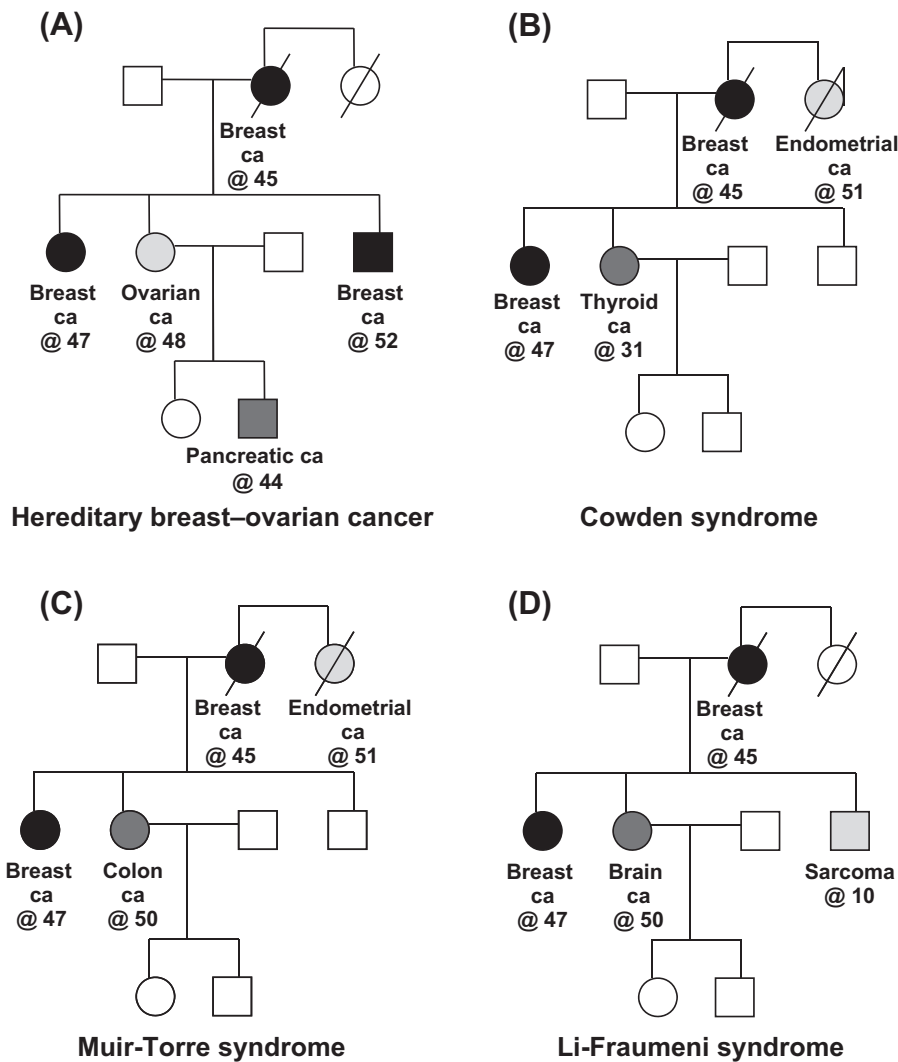

**FIGURE 20-3** Family history collection followed by risk stratification that recognizes characteristics that increase disease risk (e.g. early age at diagnosis, two or more close relatives affected by a disease or a related condition, a single family member with two or more related diagnoses, multifocal or bilateral disease, and occurrence of disease in the less-often-affected sex) can guide risk-specific recommendations for disease management and prevention. Standard public health messages would be appropriate for individuals with a weak familial risk and the absence of significant personal risk factors. Personalized prevention recommendations should be provided to individuals with moderate or strong familial risk, which should include emphasis of public health messages, consideration of earlier and more frequent screening, and use of chemoprevention when available. Referral for genetic evaluation by a geneticist or other specialist should be considered for individuals with strong familial risk or when a Mendelian disorder is suspected.

information for each family member is documented, which typically includes each relative's current age or age at death. Medical history is documented for each family member including age at diagnosis, cause of death if deceased, and known interventions or procedures, which can help clarify a diagnosis. For example, questioning regarding coronary artery bypass surgery, angioplasty, heart transplant, or pacemaker placement may help clarify a relative's diagnosis of heart disease. Information is also collected regarding important risk factors for a disease, such as the use of hormone replacement therapy in the case of endometrial cancer, chest irradiation in the case of breast cancer, and smoking, asbestos exposure, and coal mining in the case of lung cancer. Medical records are reviewed when possible to verify the medical history of each family member or at least those who are critical to the genetic risk assessment and diagnosis. The family history should include ethnicity and country of origin of grandparents, as certain conditions might be more prevalent in certain groups. For example, the prevalence of insulin resistance is high among individuals of Native American admixture (37) and Asian Indian origin (38) and there are common *BRCA* gene founder mutations in Ashkenazi Jewish families with breast and ovarian cancer (39).

Once family history is collected, the most likely mode of inheritance (i.e. Mendelian vs multifactorial) and the risk of disease to the patient and to the unaffected relatives is determined based on their position in the pedigree. When a Mendelian disorder is suspected, this analysis also helps to elucidate a differential diagnosis through pattern recognition (1). For example, when considering an inherited form of breast cancer, there are at least five different Mendelian disorders to consider,

including hereditary breast–ovarian cancer syndrome, Cowden syndrome, Peutz–Jeghers syndrome, Li–Fraumeni syndrome, and Muir–Torre syndrome. The types of cancers and other conditions reported in the family help to distinguish each of these syndromes (Figure 20-4). Mutations in different genes underlie the genetic susceptibility of these syndromes, and genetic testing can help to confirm a suspected diagnosis. For certain hereditary cancers, models are available to help predict the probability of an inherited gene mutation (40–42). For pedigrees that lack convincing evidence of Mendelian inheritance and are more consistent with multifactorial inheritance, quantitative risk information can be provided for some conditions through the use of mathematical models or published estimates that consider the family history (43–48).

Accuracy of the family history data is paramount particularly if clinical decisions will depend on the information. Many studies have shown that self-reports of family health history are relatively accurate for many common chronic conditions, such as CHD, stroke, diabetes, and many forms of cancer. Most positive predictive values for self-reports of a family history of these conditions in a first-degree relative range from 70 to 90% and negative predictive values are usually 90% or greater (49–51). These values depend on the type of disease, age of the historian, and distance of the relative from the *consultand*. Therefore, before clinical decisions are based on such information, confirmation of family health histories is advisable. Currently, such confirmation is handled by health professionals who request and review medical records, pathology reports, and death certificates of family members to verify self-reports. This can be time consuming and costly (52).

**FIGURE 20-4** Each pedigree depicts a strong familial risk of breast cancer. However, by recognition of the patterns of cancer in the family, a more accurate diagnosis can be made. Pedigree A features early-onset breast and ovarian cancer and is most consistent with hereditary breast-ovarian cancer syndrome, which is almost always due to *BRCA1* or *BRCA2* gene mutations. In this case, a *BRCA2* gene mutation is likely given the family history of male breast cancer and pancreatic cancer. Pedigree B features early-onset breast, thyroid and endometrial cancer and is most consistent with Cowden syndrome due to *PTEN* gene mutations. Pedigree C features early-onset breast, colon and endometrial cancer and suggests the possibility of Muir-Torre syndrome, a variant of hereditary nonpolyposis colon cancer due to mutations in mismatch repair genes. The early-onset breast cancer, brain tumor and childhood sarcoma in pedigree D is consistent with Li-Fraumeni syndrome due to *TP53* gene mutations. Multiple primary cancers are common among individuals with Li-Fraumeni syndrome.

### 20.2.3 Genetic Testing

Genetic testing for common diseases in clinical practice is generally limited to testing for Mendelian disorders (53). Indications for genetic testing of Mendelian disorders that feature common chronic diseases can be characterized as *diagnostic*, *prognostic*, and *predictive* of disease risk and therapeutic response (i.e. *pharmacogenetic* testing). A particular indication for genetic testing can correspond to multiple reasons for testing (Table 20-1). For example, diagnostic testing in a patient with signs and symptoms of disease may be performed primarily for medical decision making, yet it may also inform a patient's reproductive or life-planning decisions.

Diagnostic tests are typically performed to confirm a diagnosis suspected on the basis of signs or

symptoms of the condition. Diagnostic tests can also include those used for *prenatal* and *preimplantation diagnosis*. Testing for Mendelian disorders can sometimes provide prognostic information on the basis of known genotype-phenotype correlations. For example, *SOD1* gene testing can reveal information about disease progression in familial amyotrophic lateral sclerosis (54) and certain *APC* gene mutations are associated with colon polyp number and extracolonic manifestations of familial adenomatous polyposis (55). Testing for somatic genetic changes in tumor tissue is another type of prognostic genetic test; results can inform risk for recurrence and treatment options (56,57). Predictive genetic testing for common diseases is performed in asymptomatic individuals often at risk because of

a family history of Mendelian disorders of high penetrance (*presymptomatic testing*) or reduced penetrance (*predisposition testing*). Pharmacogenetic testing is another type of predictive genetic testing; it is done to predict an individual's response to a drug, including adverse reactions. Predictive testing for multifactorial conditions consisting of multiplex testing of low-penetrance alleles (*susceptibility testing*) is generally provided through direct-to-consumer marketing (58). This is likely due to limited progress in the discovery of genes for multifactorial forms of common diseases that have meaningful clinical relevance (9). Very little is understood regarding the interactions between genetic and nongenetic risk factors underlying multifactorial diseases, and attempts to build genetic risk models have failed to show that additional genetic information can substantially improve the prediction of risk for common diseases, such as diabetes or cardiovascular disease

(59,60), and evidence for improved health outcomes is lacking (61).

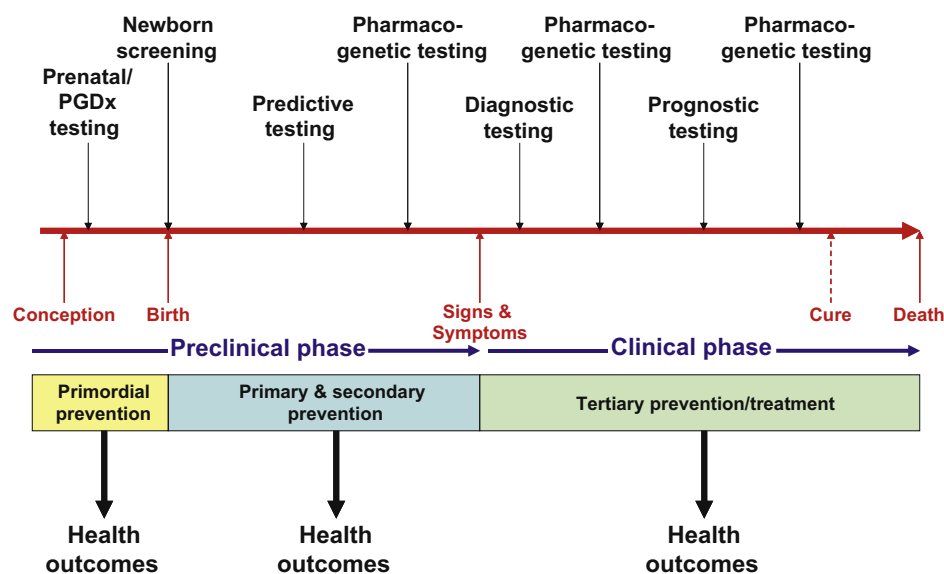

Aside from *newborn screening*, currently, genetic testing for common diseases of adulthood has a role throughout the lifespan (Figure 20-5). Most individuals undergo genetic testing for common diseases to diagnose Mendelian disorders or to learn of a risk of Mendelian disorders. Prenatal and preimplantation genetic diagnosis is less often performed for Mendelian disorders that feature common chronic diseases, mostly because of reduced penetrance, variable expressivity, adult onset, and the opportunities for prevention. Pharmacogenetic testing may be performed before or after signs and symptoms of disease occur. Carrier testing is usually performed for autosomal recessive and X-linked recessive disorders, which are not typical modes of inheritance for most common diseases (1).

The ACCE (analytic validity, clinical validity, clinical utility and ethical, legal, and social issues) framework is

**TABLE 20-1** Intended Uses of Genetic Testing Performed for Various Indications

	Medical Decision Making	Reproductive Decision Making	Personal Decision Making
Diagnostic (confirmation)	X	X	X
Presymptomatic/predisposition	X	X	X
Susceptibility	X		
Pharmacogenetic	X		
Prognostic	X		X
Carrier testing		X	
Prenatal	X	X	
Preimplantation		X	

There may be multiple intended uses of genetic testing performed for various indications, including medical, reproductive, and personal decision making. Medical decision making includes decisions regarding disease management (in fetus too), screening for early detection or prevention. Reproductive decision making includes decisions regarding conception/timing of conception, adoption, gamete donor, and pregnancy termination. Personal decision making includes decisions regarding life, career, and financial planning (does not meet the "medical necessity" criteria of most insurers).

**FIGURE 20-5** Currently, genetic testing for common diseases of adulthood has a role throughout the lifespan, including testing that can impact primordial, primary, secondary, and tertiary disease prevention. Predictive testing includes presymptomatic testing for highly penetrant Mendelian disorders, predisposition testing for Mendelian disorders with reduced penetrance, and susceptibility testing for common diseases due to multifactorial inheritance.

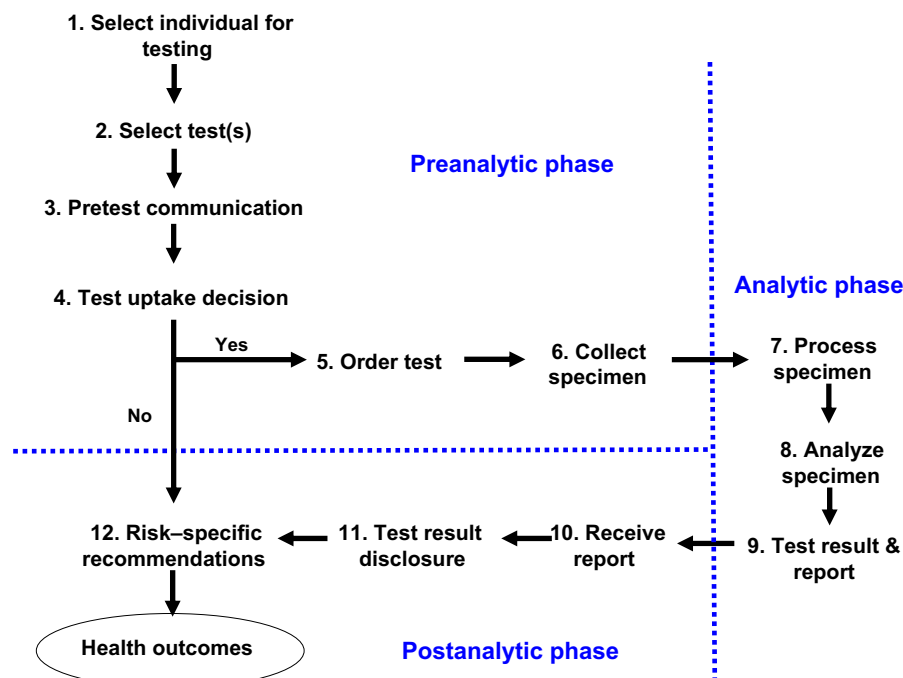

commonly used to evaluate genetic tests for common diseases (62). *Analytic validity* refers to how accurately and reliably the test measures the genotype of interest, *clinical validity* measures how consistently and accurately the test detects or predicts the intermediate or final outcomes of interest related to a genotype, *clinical utility* is a measure of how likely the test result will influence health outcomes, and the *ethical, legal, and social implications* that should be addressed are those that may arise as a result of genetic testing, such as loss of privacy, confidentiality, stigmatization, and discrimination. The disorder, setting, and clinical scenario are important considerations when applying the ACCE framework. The clinical scenario should include the purpose and indication for testing.

A framework depicting the steps involved in the delivery of genetic tests according to the preanalytic, analytic, and postanalytic phases of the genetic testing process is shown in Figure 20-6. In general, all steps should occur for any clinical scenario. The actions performed for each step may vary, depending on the genetic testing indication. The process begins with patient selection (Step 1), which will often depend on personal and family history characteristics. With this information, a differential diagnosis is developed, and in the case of predictive testing, risk assessment is provided usually based on the suspected mode of inheritance and position in the pedigree. Thus, use of family history is central to providing access to genetic testing services that are currently available, and it is likely that the paradigm of familial risk assessment will inform future genetic testing of less-penetrant susceptibility alleles. Therefore,

family history will likely remain a relevant genetic tool for many years to come (63).

Step 2 consists of identification of appropriate tests that may be helpful in confirming a genetic diagnosis and refining genetic risk. When considering genetic testing, clinicians should choose the testing strategy that would be most informative for patients and their family members. Ideally, genetic testing should begin in an affected family member to identify the specific genetic determinant(s) of disease. If an abnormality or abnormalities are identified, then at-risk relatives can be tested for those familial factors. Excluding these familial factors in at-risk relatives can provide reassurance regarding disease risk due to the family history; however, there will always be a background or population risk for disease development. It is not always possible to test an affected family member. In this case, unaffected family members may participate in testing. A normal test result can exclude the genetic risk factors that have been tested but not the possibility of an inherited susceptibility. In such a case, medical management would typically depend on the empirical risks associated with the personal and family histories. To further clarify the situation, testing additional family members, both affected and unaffected, may be helpful.

Pretest communication about testing follows in Step 3 and often includes an informed consent process that describes the potential benefits, risks, and limitations of genetic testing, as well as the alternatives to testing (see Section 20.2.5). In Step 4, a shared decision between patient and provider is made regarding genetic testing. The provider then identifies a laboratory that

**FIGURE 20-6** A framework depicting the delivery of genetic tests according to the preanalytic, analytic and postanalytic phases of the genetic testing process is shown. The specific actions of each step will vary, depending in large part on the indication for genetic testing. Yet in general, all steps should occur for any given clinical scenario.

can perform the testing and orders the test in Step 5, providing necessary information to the laboratory on the test requisition to facilitate selection of the appropriate test method and interpretation of results. Most genetic tests are performed in reference laboratories, therefore sample processing and shipping is often necessary (Step 6). Issues to consider when choosing a laboratory include methodology, analytic sensitivity and specificity, technical support, cost, and turnaround time. Understanding which methodology is used is important because standards for many genetic tests currently do not exist. There is great variability in testing procedures for many conditions. As a result, clinicians need to be familiar with a given laboratory's protocol and the test limitations.

The analytic phase includes Steps 7–9. Genetic tests for assessing common diseases are typically DNA-based tests. Most commercial laboratories performing DNA-based testing use polymerase chain reaction (PCR)-based methods to amplify the patient's DNA to be followed by sequencing or other methodologies. There are limitations to each method, and the method chosen often depends on the testing indication and purpose. Rarely, errors may occur with sample handling, contamination by airborne particles in the laboratory, or failure of the PCR technique. In most cases, sequencing is considered the gold standard for identification of an unknown mutation. However, sequencing can miss rearrangements or large deletions or duplications of DNA (64,65) or mutations affecting gene expression (66). Although successes of whole genome or whole exome sequencing are being documented (67,68), the application of these technologies to common disease is complex even in the presence of a recognized family history (69). The key challenges for bringing these technologies to the clinic are the collection and characterization of phenotype information, the incorporation of the influences of environmental and behavioral factors, and the creation of standards for utilizing this information in clinical practice (70–72).

When the genetic test results are available, the laboratory provides the ordering clinician with a test report (Step 10). A posttest consultation typically follows to review the implications of the test result for both the patient and the family members (Step 11). The genetic test results should be interpreted within the context of the individual's personal and family histories and the indication and purpose for testing, and recommendations for disease management and prevention should be specific to the risk assessment and diagnosis (Step 12).

### 20.2.4 Management and Prevention Strategies

Knowledge of genetic susceptibility to common diseases may identify important biologic differences that could lead to better disease management and prevention through the use of targeted therapies and enhanced

screening and prevention strategies. Prevention strategies for common chronic diseases include targeted lifestyle changes; screening at earlier ages, more frequently and with more intensive methods than used for average risk individuals; use of chemoprevention; and, for those at highest risk, prophylactic procedures and surgeries.

For many Mendelian disorders that feature common chronic conditions, specific guidelines for initial evaluation, management, and follow-up for affected persons and surveillance for at-risk relatives are available. However, most of these guidelines are based on clinical observation and expert opinion, and outcomes research that assesses their clinical utility is needed. Recommendations for screening and prevention based on evidence derived from clinical studies exist only for a minority of Mendelian disorders, including hereditary breast and ovarian cancer (73–75) and colon cancer (76).

In the absence of clinical guidelines for common chronic diseases associated with Mendelian disorders, clinicians can suggest management and prevention strategies that have been proved to be effective for the general population. Such guidelines exist for CHD (77), stroke (78), diabetes (79), and cancer (80,81). However, clinicians must proceed with caution, because interventions that are effective for the general population might not be effective for individuals with a genetic predisposition. For example, tamoxifen is associated with a significant reduction in the occurrence of breast cancer (82); however, women with *BRCA1* gene mutations do not appear to benefit from the use of tamoxifen for primary prevention of breast cancer (74).

Recommendations for management and prevention options for an individual with genetic risk should be communicated in writing so that the patient and the referring clinician can incorporate these recommendations into a plan for future health management. Family members who might benefit from risk assessment and genetic testing should be identified, and the clinician should facilitate communication between the index case and at-risk relatives and provide referrals to genetic professionals or other specialists for relatives. Plans for follow-up with a genetic professional may be appropriate to review the individualized plan for management of genetic risk, and updated personal and family history information can be obtained with revision of the management and prevention plan as indicated. New information and technology available for genetic risk assessment or management and prevention of disease can also be discussed.

### 20.2.5 Genetic Counseling and Education

Genetic counseling is critical for delineating a patient's motivation for genetic evaluation and likely responses to learning of a genetic risk or diagnosis. An important goal of genetic evaluation for common chronic diseases is the development of individualized management and preventive strategies based on genetic risk assessment and the patient's personal medical history, lifestyle, and

preferences. Through genetic counseling, patients will be educated about the role of genetic and nongenetic risk factors for disease; basic concepts of genetics, such as inheritance patterns, penetrance, and variable expressivity; and the options for treatment, prevention, or risk factor modification tailored to the genetic risk or diagnosis.

How genetic risk factor information may influence behavior is complex and may depend on the condition of concern, the contribution of the genetic factor to risk or severity of disease, and personal beliefs about the role of genetics (83). There is evidence that awareness of increased risk due to family history does not automatically translate to spontaneous improvement in lifestyle choices. For example, in young adults, the occurrence of a heart attack or stroke in an immediate family member did not lead to self-initiated sustained change in modifiable risk factors (84) and among low-income, rural African-American women who had not had a recent mammogram, knowledge of family history of breast cancer was not associated with perceived risk or screening (85). These results suggest that consumers may not appreciate how genetic and familial risk factors relate to their disease risk, or they may not be aware that despite a genetic predisposition there are actions that they can take to lower their risk. Genetic counseling and education may be necessary to actively intervene in people with a genetic susceptibility to common chronic diseases.

Genetic counseling also ensures the opportunity to provide informed consent, including discussion of the potential benefits, risks, and limitations of testing; implications for family members; and the alternative of not testing. A benefit in knowing of a genetic predisposition through genetic testing is the potential to improve diagnosis, management, and prevention efforts for individuals and their family, and there may be psychological and cognitive benefits as well (12–15). Potential risks relate to family issues that may arise with genetic testing for common chronic diseases (86). Family members may experience loss of privacy when asked to share their medical history and medical records, and if labeled as having a genetic predisposition to disease, family, friends, or society may stigmatize them. Family dynamics may change from the knowledge of a genetic risk for disease. For example, a parent may feel guilt about passing on a disease predisposition or a sibling may experience survivor guilt if a genetic susceptibility is excluded for them but identified in another sibling. There is also the concern that third parties such as employers, educators, and insurers could use genetic information to exclude individuals from employment or education opportunities or from obtaining health, life, long-term care, or disability insurance, and this concern has had a negative impact on the utilization of genetic services (87) despite the lack of evidence of genetic discrimination against otherwise healthy individuals (11). It is hoped that the Genetic Information Nondiscrimination Act (GINA) of 2008, (88) which provides new legal protections from

genetic discrimination by employers and health insurers, will mitigate some of these concerns.

### 20.3 INTEGRATING GENETIC INFORMATION INTO ROUTINE CLINICAL PRACTICE

Attempts to integrate genetic/genomic knowledge of common chronic conditions into routine clinical practice are still in the early stages. The primary care setting is ideal for initial genetic risk assessment. Primary care clinicians play a major role in assessing risk factors and providing preventive services. The role of primary care providers in providing genetic services may vary depending on their knowledge and comfort with the steps involved (Figure 20-6). But in general, primary care should be prepared to identify patients who may benefit from genetic services, provide basic genetic information to facilitate the referral process for patients with complex genetic services needs, recognize the special psychosocial issues for a family with a genetic condition and coordinate care and monitor the health of patients with genetic conditions (89).

Unfortunately, primary care clinicians lack knowledge and confidence relating to provision of genetic services, including assessment of familial risk, ordering and interpreting genetic tests, and recommending referral and risk-specific interventions (90). Significant barriers relate to the use of the family history, including clinicians' lack of time and perceived lack of knowledge and skills to collect and interpret family history and lack of sufficient evidence on how to perform familial risk assessment and the effects of familial risk on clinical outcomes (91,92). These barriers could be overcome in large part through the use of family history tools (e.g. stand-alone tools or applications integrated into electronic health record and personal health record systems) that have the capabilities to facilitate collection of relevant personal and family health history in a structured format, organize the data in a usable form such as a graphic display following pedigree drawing standards, interpret the familial risk and recognize patterns of familial disease suggestive of inherited susceptibilities (i.e. pedigree analysis), and recommend interventions that are tailored to the familial risk and personal factors. However, most electronic health records have not integrated family history in such a way as to meet the needs of clinicians (93). Data elements and functionality requirements that clinicians would like to see include pedigree drawing, clinical decision support for familial risk assessment and genetic testing indications, a patient portal for patient-entered data, and standards for data elements, terminology, structure, interoperability, and clinical decision support rules.

Results of a national survey show that most Americans believe that knowing family history is very (73%) or somewhat (24%) important to their personal health, yet only a minority actively documents their family history (94). Efforts such as the Surgeon General's Family History

Initiative have begun to raise awareness among the public and health professionals about the value of family history (95). In 2004, the US Surgeon General declared Thanksgiving as the National Family History Day and encouraged Americans to collect their family members' health histories and share the information with their health care providers. A web site was created with educational materials as well as a family history data collection tool. A validation study found that the Surgeon General's family history tool has high sensitivity and specificity for family history documentation, with values ranging from 67 to 100% and 92 to 100%, respectively (96). In addition, familial risk assessment conducted by experts using the data obtained from the tool vs data obtained by the experts were identical in 94–99% of the pedigrees with a history of diabetes and colon, breast, and ovarian cancers but were lower for pedigrees with coronary artery disease (68%) and stroke (83%). Family Healthware is another web-based tool developed by the Centers for Disease Control and Prevention (97). Family Healthware collects family health history and information about preventive behaviors, estimates familial risk for six common diseases, and provides users with individualized prevention messages that incorporate their familial risk assessment. This tool was assessed for impact on health behaviors in a randomized trial and demonstrated modest beneficial effects on dietary and physical activity behaviors (98).

## 20.4 SUMMARY

Genetic factors play an important role in the etiology, natural history, and response to therapy for many common diseases. Knowledge of the genetic factors contributing to common diseases can provide the basis for recommending alternative disease management and enhanced preventive strategies. Currently, the family history is the best initial approach for genetic risk assessment of most common chronic diseases. Genetic testing can then be used to further refine the genetic risk assessment, diagnosis, and management decisions. Primary care clinicians are best suited to identify patients with increased familial risk, with referral of high-risk cases or those suspected of having a Mendelian disorder. However, barriers for primary care include the lack of time and the perceived lack of knowledge and skills to collect and interpret family history. Electronic family history tools have the potential to mitigate these barriers. More translation research is needed to develop the evidence base necessary for integration of genomic medicine into the routine health care for common diseases.

### Biographies

**Dr. Shannon L Rhodes** received her PhD in Epidemiology from UCLA and completed a post-doctoral fellowship at the Cedars-Sinai Medical Center in the Division of Medical Genetics Common Diseases research group. Dr. Rhodes is a genetic epidemiologist in the Ritz research group at the Department of Epidemiology at UCLA where she participates in gene finding and gene–environment interaction research in Parkinson’s disease. Dr. Rhodes is also a research health scientist at the VA Greater Los Angeles Healthcare System where her research activities focus on appropriateness and utilization of genetic testing services.

**Dr. Maren T Scheuner, MD, MPH, FACMG** is a clinical geneticist and health services researcher at the VA Greater Los Angeles Healthcare System, an Associate Health Sciences Professor in the Department of Medicine at the David Geffen School of Medicine at UCLA, and a natural scientist at the RAND Corporation. She is trained as an internist and medical geneticist and specializes in the field of common disease genetics. She is a member of several national committees that address education and quality improvement in genetic medicine, including the Board of Directors of the American Board of Medical Genetics and the National Coalition for Health Professional Education in Genetics. Her research addresses topics relating to health services and policy research in genetic/genomic medicine, including assessment of genetic/genomic technologies; the intersection of health information technology and genomics; development and evaluation of family history tools for public health and preventive medicine practice; implementation, surveillance, and outcomes research in medical genetics/genomics; and health professional education in genetics.

### 21.1 WHAT IS GENETIC COUNSELING?

#### 21.1.1 Evolving Definitions

A discussion of what constitutes genetic counseling quite naturally begins with the definition posed by the person who coined the term in 1947, Dr Sheldon Reed. Dr Reed, who held a PhD in human genetics, stated that “The primary function of genetic counseling is to provide people with an understanding of the genetic problems in their family” (1,2). As the director of a hereditary disease clinic at a time when being able to test for or treat a genetic disease was the exception rather than the rule, it makes sense that his definition focused on the social rather than medical aspects of the encounter (3). He recognized the importance of providing families with accurate information to promote understanding. However, he also appreciated the myriad of emotions generated by genetic diagnoses, and the necessity of addressing these (4). Furthermore, the definition, with its focus on people, rather than populations, distanced genetic counseling from both eugenics and a public health model of service provision.

Since this first description of genetic counseling, a number of definitions have been developed by individual practitioners and professional organizations to reflect the evolution of genetic services. In 1975, the American Society of Human Genetics (ASHG), whose members include researchers, medical geneticists, clinical geneticists and genetic counselors, defined genetic counseling as “...a communication process which deals with the human problems associated with the occurrence or risk of occurrence of a genetic disorder in a family.” The definition states that “appropriately trained persons” help individuals or families “comprehend medical facts,” “appreciate

the way heredity contributes to the disorder and the risk of recurrence,” “understand the alternatives for dealing with the risk,” choose their own course of action, and “make the best possible adjustment” (5). This definition, similar to Reed’s, emphasizes the importance of information in helping clients understand and cope with a genetic condition or risk. The definition adds a statement about the importance of informing families about their options for managing genetic risk. These options, including prenatal diagnosis and the legal right to terminate a pregnancy, were largely not available in 1940s and 1950s. The definition highlights the importance of letting clients make their own decisions regarding these alternatives, further distancing clinical genetics from its eugenic roots.

In the years following the publication of the ASHG definition, genetic counseling services have expanded into new arenas. Genetic counseling is occurring in settings beyond reproductive and pediatric genetics clinics. Increasingly, family medical history and genetic testing can be used to identify individuals at increased risk for common, adult-onset diseases. For some of these, identification of genetic risk guides clinical management strategies that can reduce morbidity and mortality. Such situations require that the clinician takes a more active role in promoting informed decision making. In response to these changes in practice and an identified need to clarify the goals of genetic counseling, in 2003, the National Society of Genetic Counselors (NSGC) convened a Definition Task Force. After a thorough review of existing definitions, the Task Force concluded that a new definition of genetic counseling was needed. The following definition, which was developed with input from the NSGC membership and a wide variety of stakeholders, was adopted by the NSGC Board of Directors in 2005 (6).

“Genetic counseling is the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. This process integrates the following:

- Interpretation of family and medical histories to assess the chance of disease occurrence or reoccurrence.
- Education about inheritance, testing, management, prevention, resources, and research.
- Counseling to promote informed choices and adaptation to the risk or condition (6).”

The NSGC definition adds to the previous definitions in important ways. First, it uses the phrase “genetic contributions to disease” in recognition of the expanded role of genetic counseling in complex (multifactorial) diseases (6). Second, it relates that education in genetics extends to prevention. Prevention is a word that is appropriately avoided when genetic counseling is discussed in the context of reproductive decision-making; however, it is a critical component of the educational process in cardiovascular genetics, cancer genetics, and other preventable adult-onset diseases. Despite these additions, the Reed, ASHG, and NSGC definitions are similar in two important ways. They all emphasize the importance of helping people understand and adapt to the genetic information.

### 21.1.2 Goals and Approaches to Genetic Counseling

As the above review of key definitions has shown, despite big changes in the scope of medical genetics services over the past 60 years, promoting understanding and adaptation remain fundamental goals of genetic counseling. All three definitions allude to or specifically state the importance of education in achieving these goals. The NSGC definition is the only one that explicitly states the role of counseling (6). However, its role is implied in Reed’s description of genetic counseling as a “kind of genetic

social work” (1). Furthermore, it may be implied in ASHG’s description of genetic counseling as a “communication process” dealing with “the human problems” associated with genetic conditions (5).

Joan Marks, director of the first genetic counseling program at Sarah Lawrence College, recognized early in the program’s history that “The hallmark of training genetic counselors is based on the premise that understanding the emotional component of genetic risk is central to providing good genetics services” (7). To prepare her students to accomplish this task, she developed a counseling curriculum to complement the science one. She used Carl Rogers’ Client-Centered Therapy, adopted from mental health counseling, with its emphasis on the counseling relationship, facilitative conditions (empathy, unconditional positive regard, genuineness), and a non-directive approach as theoretical basis for a course on interviewing (7,8). As such, elements of Client-Centered Therapy, later named Person-Centered Therapy, were incorporated into genetic counseling practice.

Others have since proposed models specific to genetic counseling. Seymour Kessler described the education (teaching) and the counseling models of genetic counseling as two distinct approaches with differing goals (9). Table 21-1 describes the goals, assumptions, tasks and relationships in each model. His impression was that genetic counselors “... attempt to combine aspects of both approaches with, I suggest, limited success, since the fundamental philosophies and professional demands of each seldom mesh ...” (9).

The counseling model, as described by Kessler, seems more flexible and to provide a more personalized approach to genetic counseling. In addition, counseling patterns of interaction may be associated with greater client satisfaction (10). Nonetheless, studies investigating the use of both approaches show that the teaching model predominates (10,11). There can be significant variation between genetic counselors in terms of the proportion of teaching

**TABLE 21-1 Comparison of the Genetic Counseling Teaching Model and Counseling Model**

	Teaching Model	Counseling Model
Goals	Educated clients	Understand the client, bolster sense of competence, promote greater sense of control, support, relieve psychological distress, help client find solutions
Perception	Clients seek information	Clients come for genetic counseling for complex reasons (information is only one of these)
Assumptions	Informed clients should be able to make own decisions	Complex assumptions about human behavior and psychology
Priorities	Cognitive and rational processes emphasized over human behavior and psychology	
Counseling task	Provide balanced, impartial information; correct misinformation	Counseling tasks are complex and require assessing client situation, using a range of counseling skills, individualizing sessions, and self-awareness/health
Relationship with client	Based on authority, counselor as teacher	Mutuality
Role of education	Education is an end in itself	Education is used as a means to achieve goals

Adapted from Kessler S (9).

versus counseling strategies used in a session. Furthermore, individual counselors may have a preferred style, which they use independent of client characteristics (12).

Having a clearly defined model of practice is important because it describes how a service is delivered and why it is delivered in this way. It incorporates the commonly held principles and beliefs of its practitioners (tenets), the goals of the clinical activity, and the strategies and behaviors (techniques) used to meet those goals (13). Importantly, it also provides a framework for evaluating the effectiveness of the activity through research. Many have advocated for the genetic counseling profession to develop its own specific model or models of practice. With the increased emphasis on evidence-based medicine, having a testable model (or models) that can be used to evaluate what works, what does not work, which strategies are essential and which may be more situation-dependent is of critical importance to the field.

Recognizing the value of a practice model, McCarthy Veach et al. (13) convened a group of North American genetic counseling program directors for the purpose of describing explicitly the current model of genetic counseling practice. The group was charged with describing the tenets, goals, strategies and behaviors for addressing clients' genetic concerns and to identify variations in the model related to genetic counseling indications or client cultural background. Using a consensus building process, the group identified five tenets. For each tenet, 3–4 goals were described. Some goals were related to the process of genetic counseling—the conditions that must be met for successful outcomes. Some goals were related to the outcomes (end results). The five tenets are as follows: information is key; relationship is integral to genetic counseling; patient autonomy must be supported; patients are resilient; patient emotions make a difference.

The tenets and goals identified through the above activity were developed into a model of practice called the reciprocal engagement model (13). The genetic counselor–patient relationship is the central component of the model because it is through this relationship that education occurs, individual attributes (supporting patient autonomy, patient resilience and emotions) are considered, and genetic counseling goals are met. The model is reciprocal because each component affects the others. The word engagement is used to stress the importance of both the patient and the genetic counselor participating in the process.

There are limits to the proposed reciprocal engagement model and it is still a work in progress. However, the development and implementation of such a model is a critical step in evaluating the effectiveness of genetic counseling strategies for all who provide genetic counseling.

### 21.1.3 What About Nondirectiveness?

Nondirectiveness has been a component of genetic counseling for several decades and in the past, it has been

described as its central ethos or guiding principle. The purpose of nondirectiveness was to distance genetic counseling from eugenics and to put decision-making authority into clients' rather than practitioners' hands. However, over the years, there have been numerous critiques of nondirectiveness. One critique is that there are a number of different definitions, some broad and some narrow, the use of which may have different practice implications. Another is that a nondirective approach may result in providers failing to adequately address the moral and ethical issues that clients face in making decisions about genetic information. Furthermore, the approach might deter a counselor from actively engaging with clients in exploring their feelings, perceptions, values and beliefs and how these factors affect the decisions to be made. The third critique is that although aspects of nondirectiveness may be applicable to reproductive genetic decision making, they may not apply in areas such as cancer or cardiovascular genetics. Fourth, some consider nondirectiveness as a model of practice, which it is not, and this may hinder the development of real practice models (14). Such critiques and a growing body of literature have led genetic counselors to question the role of nondirectiveness in the genetic counseling process.

In 2003, at the Annual Education Conference of the NSGC, a workshop was held to discuss the relationship of nondirectiveness to genetic counseling (15). Participants identified the value of nondirectiveness including its historical relevance, value as an ethical stance, and its use to promote client autonomy. They also identified several limitations, similar in scope to the ones listed above. On the basis of the discussion, the workshop leaders made several suggestions. First, they indicated that it is important to clarify what the role of nondirectiveness is and what it is not. It may be a component of the ethical basis of practice that promotes client autonomy and encourages counselors to pay attention to the myriad of factors that have an impact on client decision making. However, it is not a theory of practice. Second, genetic counselors must use "... flexible, interactive, skill-based counseling ..." to be effective (15). They should not let narrow definitions of nondirectiveness prevent them from doing so. Third, as genetic counseling expands into new practice settings, it will be important to identify whether traditional genetic counseling approaches work or whether new approaches are needed. The workshop leaders closed with encouraging genetic counselors to evaluate practice models that other professions have used to successfully integrate psychosocial and medical information.

In summary, there are still elements of nondirectiveness that remain important to genetic counseling, namely promoting patient autonomy and attaching importance to clients' values over genetic counselors'. These elements are particularly important in settings such as reproductive genetics. However, the term nondirectiveness, without a clear definition, should not be the guiding

principle of genetic counseling. Furthermore, it is not a model of practice; it may deter genetic counselors from fully engaging with clients, and may not work well in some practice settings. Efforts to better define the guiding principle(s) and models of practice of genetic counseling are underway. These efforts have the potential of enhancing the effectiveness of genetic counseling in a way that nondirective approaches cannot.

### 21.1.4 Indications for Genetic Counseling

With the expansion of genetic testing and the understanding of genetic factors in common diseases, the indications for genetic counseling services have grown. Genetic counseling remains important for single-gene disorders such as cystic fibrosis (CF) and Huntington's disease but it has become increasingly important in communicating genetic information that can influence the expression of multifactorial and adult-onset conditions such as cardiovascular disease. One hope is that with an understanding of genetic factors that influence the expression of multifactorial conditions, individuals will be empowered to make wise health choices to reduce their disease risk and health care providers will be able to provide individualized medical management that considers an individual's physical health and genetic risk factors to a disease to optimize an individual's health and medical management.

The three primary indications for referral for a genetic evaluation fall into the general categories of reproductive genetics, pediatric genetics and adult onset disorders. Referral patterns are also rapidly evolving to include many more adult-onset disorders in addition to cancer and other multifactorial conditions, in which the genetic basis is better understood utilizing the advances in molecular genetics. Common goals of many of these evaluations are to establish if an individual is affected with a single-gene disorder or determine the genetic risk factors, provide recurrence risk counseling for themselves and family members, to assist in medical management of the disorder and to provide education about the condition and related issues.

In many cases, it is the general practitioners such as a pediatrician, internal medicine physician or family medicine physician who identify a patient in their practice with a potential genetic concern and then refer them for a genetic evaluation. Therefore, it is important for all health care professionals to be knowledgeable about the conditions and findings that are common to their discipline that might suggest an individual has a genetic condition or risk factor. There are numerous recommendations and guidelines for appropriate referrals for genetic counseling and genetic evaluation published by genetics organizations from around the globe (Table 21-2). Providers are advised to be familiar with any genetic practice guidelines or policy statements related to their specific discipline published by their own professional organization.

### 21.1.5 Who Provides Genetic Counseling?

Genetic counseling services are provided by a variety of health care professionals in a number of different settings. In some settings, such as to pediatric genetics, metabolic disease, and specialty disease clinics, services are often provided by the genetics team. This team is composed of professionals trained in various aspects of genetics including clinical (MD) geneticists, genetic counselors, genetic nurses, and medical (PhD) geneticists with laboratory support from cytogeneticists, molecular geneticists, and biochemical geneticists. Other key professionals such as nurses, dietitians, social workers, and/or psychologists can also be members of the team. Each team member has his/her own set of skills and corresponding role in the team although there can be some overlapping functions. Various team members may contribute to the interpretation/risk assessment, education, and counseling functions of genetic counseling. This role is not limited to genetic counselors.

In reproductive genetics, genetic counseling services are often provided by genetic counselors or genetic nurses working with geneticists or with physicians boarded in obstetrics or maternal fetal medicine specialists. Similarly, in adult onset disorder clinics, genetic counselors may work with a variety of specialists including but not limited to oncologists, surgeons, gastroenterologists, cardiologists, or neurologists.

In the examples above, at least one health care professional has formal training in a genetics specialty. However, as the availability of and demand for genetic testing have increased, and as applications of genetic testing have expanded (e.g. population-based carrier screening programs, pharmacogenetics testing), more

pressure has been exerted on all health care professionals to provide some level of genetics services. Deficits in medical genetics knowledge have been identified as barriers to provision of appropriate genetics services (16). Some health professions and specialty groups are working to overcome the knowledge deficits. For instance, physician assistants have developed genomics competencies (17) to incorporate into their training programs. Nursing groups have defined genomics competencies for different levels of nurses (18). The National Coalition of Health Professional Education in Genetics has developed core competencies in genetics, now in their third edition, for all health care professionals (19). Organizations such as the American Society of Clinical Oncologists have stated their commitment to providing educational opportunities in genetics (20).

In the face of such efforts, the question becomes where does the role of the primary health care provider end and where does the role of the genetics professional begin? What situations should be managed in primary care and when should a patient be referred for genetics services? Some organizations, such as the American College of Obstetrics and Gynecology (ACOG) and the American Academy of Pediatrics, provide guidance to their membership regarding these questions through policy statements, practice and education bulletins and committee opinions. But this is an area where genetics professionals should also have a strong voice. Working collaborations between genetics professionals and other health care providers are required if the goal of ensuring that patients have adequate and appropriate access to genomics services is to be achieved.

## 21.2 PROCESS OF GENETIC COUNSELING

As the NSGC' definition delineates (6), the process of genetic counseling involves interpretation of family and medical history to assess risk, education, and counseling. This is accomplished through five basic tasks: information gathering, risk assessment, information giving, psychosocial assessment and counseling, and management/follow-up. The following sections describe how these components are integrated throughout the genetic counseling process.

### 21.2.1 Information Gathering

**21.2.1.1 Presession Information.** Information gathering often begins before the genetic counseling session takes place. In some cases, the genetic counselor (this term will be used to denote any professional involved in genetic counseling) may have the opportunity to speak to the client before the session to request records, to inquire about the client's goals, to collect preliminary family history information, or to answer questions about the visit. In others, the genetic counselor

gathers information indirectly, from details collected by an administrative staff person upon scheduling the appointment, from medical records, from a completed family medical history questionnaire, or from a conversation with a referring physician. Such information can help the genetic counselor to begin assessing the nature of the genetic risk, the client's experience with the condition or concern, and potential client goals for the genetic counseling session. However, as pressures to work more efficiently increase, genetic counselors may no longer have the luxury to gather and review this information in depth precounseling.

Whether first contact occurs by telephone presession or at the time of the encounter, it is important to remember that, with perhaps the exception of prenatal diagnosis, most people are not familiar with genetics services. As such, a referral can generate feelings of anxiety, fear, shame, or anger. Furthermore, if the client feels coerced into the referral by his/her primary care provider or family, he/she may also be resentful. The referral may confirm fears that a family already has about a specific diagnosis, such as muscular dystrophy, or introduce the possibility of a previously unheard-of condition or risk. Unlike other types of referrals, a genetics referral raises fears not only for the potentially affected individual but also for other family members—born and unborn. Even a person who has self-referred may have taken years to work up the courage to call and request testing or counseling. Thus, it is critical that the basis for future open communication and trust be established at this point.

**21.2.1.2 Contracting: Setting a Mutually Agreeable Agenda.** Once initial introductions have been made, the next step of the genetic counseling session is contracting. Contracting is the process of identifying the client's main questions, concerns, and goals for the session for the purpose of setting a mutually agreeable agenda. The process begins by determining what the client or family understands regarding the reason for referral. What were they told regarding the purpose of the appointment? What has their health care provider shared about his or her concerns? Does the individual or family share these concerns or do they feel the appointment is unwarranted? Was a specific diagnosis mentioned? If so, what were they told about the likelihood of this diagnosis or about its implications? What information has the individual or family gathered about the condition or risk before the appointment? This question becomes increasingly important given the easy accessibility of both high- and low-quality information on the Internet.

Such questions help the genetic counselor ascertain the client or family's grasp of the situation, motivations for genetic services, and expectations. They also set the stage for developing the session goals and agenda and for providing realistic expectations. For instance, a woman who is referred for a positive maternal serum screen may indicate that she was told her baby has Down syndrome.

In this case, the first priority becomes explaining that the test indicated an increased chance but not a certainty of the diagnosis. A family may present to pediatric genetics thinking that their child finally has an established diagnosis and they will simply be learning about the condition when in reality, the purpose of the session is to determine if the diagnosis can be made. In this case, the genetics professional has to clarify session goals and potentially manage the family's emotional reactions to the possibility of no diagnosis. A woman may present for cancer genetics services indicating that her physician told her she had to have counseling before having genetic testing for hereditary breast cancer. In this situation, it is important to clarify the purpose of counseling in the context of accurate risk assessment and genetic test selection. It may also be beneficial to the working relationship to help the woman recognize that she has some control in setting the session goals.

Once the counselor has ascertained the client or family's perceptions and expectations, the next step is to develop specific and realistic goals and a road map for achieving those goals (agenda). In outlining the goals and agenda, it is important to include what the consultation will entail, who will be involved and the various roles of these team members, and what types of additional investigations (e.g. genetic tests, medical tests, information from other relatives) may be necessary. It is also important to let the individual or family know what is expected of them. Informing them of their role in providing information puts some ownership of the session outcome in their hands and can make the session more collaborative. Inviting them to ask questions and explaining that questions are expected also set the stage for collaborative, client-focused genetic counseling. The goals and agenda should be offered tentatively to give the client license to provide input. Once the counselor and client have reached mutually agreeable session goals and agenda, the work of the session can begin. The counselor should check in with the client periodically to assess whether the session goals remain the same and the agenda still makes sense. If goals or objectives change because of newly identified information or concerns, the counselor should be flexible and modify the agenda accordingly.

Is contracting really important? From a practical standpoint, it is. Even when individuals or families present for genetic counseling with the same indication, their goals and expectations can be quite different. For instance, in one pediatric genetics clinic day, two families presented for evaluation and counseling because they each recently had a baby diagnosed with Down syndrome. One couple received the diagnosis prenatally. They had already identified the early intervention services available to them, their child had had much of the recommended medical follow-up, and they had made contact with other families who have children with Down syndrome. Their primary goal was to make sure their child was obtaining all the medical services indicated. In

contrast, the second couple received the diagnosis after birth. The pregnancy was unplanned and the mother was working on her graduate dissertation when the baby was born. This couple was overwhelmed by the unexpected diagnosis, the demands of a new baby (the couple's first), multiple appointments with various health care professionals, and graduate school responsibilities. They were unable to articulate session goals but it was clear that one goal would be to help them identify sources of support. By gathering the necessary information, the counselor was able to identify each couple's major concerns and manage the cases accordingly. Case examples aside, there is also evidence in the medical literature that contracting is important. For instance, one study found that genetic counselors were not always accurate in assessing client's concerns and that client satisfaction with genetic counseling was lower in these cases (21).

In summary, contracting, which involves gathering information about clients' questions, concerns, and goals, and then using the information to develop a mutually agreeable agenda, is an important part of the genetic counseling process. Failure to tailor genetic counseling sessions may result in failing to meet clients' needs and expectations. It may also result in decreased client satisfaction.

**21.2.1.3 Collecting Family and Personal Medical History.** The family medical history, as captured in the genetic pedigree, is considered the cornerstone of genetic counseling. In addition, it has been recognized as an important part of personalized medicine approaches (22). The pedigree serves many functions. It can be used to establish a diagnosis, identify a pattern of inheritance, calculate genetic risks, distinguish between genetic and nongenetic risk factors, and identify healthy relatives who could benefit from medical screening tests (23). The pedigree also provides an excellent snapshot of how both genes and environment interact in a given family to cause disease. Furthermore, identifying a client's risk for disease through pedigree analysis can provide valuable information about the positive predictive value of a screening testing or genetic test for that disease in the individual (24).

The pedigree is also a valuable tool for establishing rapport with clients. It puts the client in the role of expert and encourages participation in the genetic counseling process. In addition, collecting family history information provides clients an opportunity to explore and share their unique perspectives on what it has been like to have a medical condition in the family. Does the family view the condition as mild or severe? What are the family's opinions regarding identification of those at high versus low risk of the condition? What are the family's opinions about acceptable versus unacceptable ways to manage risk? How are the client's views similar or dissimilar to other relatives' views? This information can help the counselor understand what having a genetic condition has meant to the family. It can help the counselor identify accurate conceptions and misconceptions. Such

information is beneficial to the counselor in tailoring the counseling session and in assessing whether the decisions clients are making about genetic risks are consistent with their experiences, perceptions, voiced opinions, values, and beliefs. It can also help the genetic counselor provide anticipatory guidance should the client choose to manage his or her risk in a way that is different from how other relatives have done so.

The pedigree can also be useful as a tool for educating the client about the condition in the family (23). The graphical representation of the family history that a pedigree provides can help the genetic counselor explain the pattern of inheritance in the family. Concepts such as variable expressivity and reduced penetrance can be demonstrated with examples taken directly from the history. When relevant, the impact of environmental risk factors can be pointed out and discussed.

A detailed account regarding how to collect family history information, including what questions to ask, how to ask them, and how many generations to include is available (23). Standardized pedigree nomenclature has been adopted and should be used (25). Depending on the purpose of the pedigree, the types of questions asked and the amount of detail sought will vary. Targeted questioning—asking questions directly related to the indication for genetic services or symptoms of the condition in question—may enhance the quality of information received about the family and may aid in establishing a diagnosis or providing an accurate risk assessment.

Despite the many potential benefits of collecting family history and developing pedigrees, there are some limitations. A pedigree is only as good as the information provided. Some clients will be poor historians. These individuals may not be familiar with their family medical history, may not have contact with a portion of the family, may not understand what type of information the counselor is trying to collect, or may be hesitant to share what they view as sensitive information. Some clients may be willing and able to collect extensive family history information but because they were unaware that they would be asked to provide it, are unprepared. Even with good historians, the accuracy of the medical information provided tends to be highest for close relatives and lower for those more distantly related. Therefore, medical record confirmation of key diagnoses can be a helpful and, in some cases, an essential part of risk assessment. It is also important to keep in mind that family history information is dynamic. As such, risk assessments may change over time. For instance, what appeared to be a low risk history can become high risk as more relatives are diagnosed with a condition. This is especially relevant when family history is being used to assess risk of adult-onset disorders.

There are several ways in which a genetic counselor can improve the quality of family medical histories. Explaining the relevance of the pedigree and why certain information is being collected, especially when this information is construed as sensitive, is important. Informing

clients in advance that family history questions will be asked can be helpful. Sending family history questionnaires or links to web-based questionnaires to clients before their appointment and encouraging them to reach out to their relatives to collect medical histories may enhance the quality of the information received. Using client-friendly language in inquiring about conditions or symptoms and adopting the language, the client uses to describe these can also help. Addressing concerns about the confidentiality of the family history information may also be important in promoting client disclosure of such information. Finally, given the dynamic nature of family history, it is good practice to encourage clients to update their histories regularly and to recontact their health care professional if notable changes occur.

### 21.2.2 Psychosocial Assessment and Counseling

Kessler stated that the counseling component of genetic counseling is primarily concerned with three tasks: understanding the client, communicating that understanding back to the client, and when possible, empowering the client feel better about herself or the situation (26). But how is this achieved in genetic counseling and what skills are needed? A genetic counseling practice analysis, conducted by the American Board of Genetic Counseling for the purpose of delineating the skills and activities associated with genetic counseling, provided a detailed description of how genetic counselors in the United States and Canada currently achieve this (27). Twenty-one tasks were identified under the major content domain of psychosocial assessment and support (27) (Table 21-3).

These activities and the skills needed to accomplish them do not appear to be specific to North American genetic counseling services. In reviewing 56 international genetic testing guidelines to determine what constitutes ideal genetic counseling, Rantanen et al. (28) found that a majority mentioned the importance of psychological support. Having appropriate education and training not only in genetics but also in communication and counseling skills was deemed valuable in that such training provides the basis for relationship building between the counselor and client, enhances the counselor's ability to understand the client's needs, and supports the counselor's role in facilitating decision making (28).

Why is the psychosocial aspect of genetic counseling important? Referrals for genetic counseling are often associated with a variety of emotions including anger, anxiety, guilt, shame, or grief/loss. Furthermore, some people who present for genetic counseling are in crisis, especially when the situation that precipitated the genetic counseling referral is unexpected and/or requires that a difficult decision be made in a short period of time. Strong emotional reactions can preclude clients from being able to listen to and fully understand the genetic education provided. In such cases, identifying and acknowledging

**TABLE 21-3 Psychosocial Assessment and Support Tasks in Genetic Counseling**

Adapted from Hampel et al. (27).

the client or family's emotional responses to genetic information is the first step to promoting informed consent, facilitating decision-making and promoting adaptation.

Psychosocial aspects are also important because referrals are often related to emotionally charged subjects including illness or disability, loss (of health, life, or desired outcome), and childbearing. To achieve the goals of genetic counseling, the counselor must understand what a diagnosis or risk means to the individual and family based on their experiences, worldview, values and goals. It is important to consider both the individual and family because genetic conditions can have an impact on both. Furthermore, the family itself and its place in the life cycle can have a significant impact on how an individual perceives and adapts to a condition or risk (29). For instance, the diagnosis of a disabling condition in the person who is the primary breadwinner in a family has different implications than when the diagnosis occurs in a young child. In both situations, the family faces significant change, but the challenges are different.

How much the counseling aspects of genetic counseling should be emphasized? This question is a source of considerable debate. In reality, the degree of emphasis is usually determined by the training of the professional involved and his or her level of comfort and perceived competence in this area. The clinical situation itself may also dictate the practicality and necessity of counseling- versus teaching-based approach. For example, employing a counseling-oriented model may be very beneficial for some couples who have elected pregnancy termination for a fetal abnormality. In contrast, there may be less need or opportunity for this approach in the preliminary counseling for prenatal diagnosis related to advanced maternal age.

The needs of the individual client can also have an impact on to what extent the counselor uses a teaching- versus counseling-oriented approach. Most clients who present for genetic counseling are psychologically not different from people in the general population. They usually are seeking information about genetic issues, not

psychotherapy. In fact, some will very clearly state up front that they do not need "counseling." On the other hand, there are many unique challenges to a person's psyche that are inherent in the issues raised by genetic counseling, the decisions clients are asked to make, and the risk or occurrence of a genetic condition or birth defect. Some of these are unlike anything most individuals have ever encountered. It is incumbent on the genetic counselor to recognize and address the common emotional reactions to these psychic challenges, even if at face value, the client is not asking for such an intervention.

A genetic counselor is typically able to manage the psychological reactions of most of his or her clients. However, when issues arise that are beyond the counselor's counseling expertise, he or she must be able to recognize this and make an effective referral to the appropriate mental health professional. It is worthwhile to understand the differences between therapeutic approaches and to cultivate good working relationships with therapists, including licensed counselors, psychologists, and psychiatrists, who have demonstrated interest in and sensitivity to genetic issues. Among these are also clergy, who, through pastoral counseling, can provide a spiritual dimension that some clients will find more comforting than other counseling approaches.

**21.2.2.1 The Process of Psychosocial Assessment.** A psychosocial assessment begins at intake. The genetic counselor can start to hypothesize potential factors that may affect the counseling interaction based on the indication for services. Reviewing medical records, when relevant, can provide insight into the client's state of health, what has transpired before the referral, and clients' experiences with the health care system, any of which can have an impact on genetic counseling. Medical records, a referral letter, or the genetic clinic's own medical/family history questionnaires can help the counselor begin to identify provider and/or client expectations for the session.

First contact is an opportunity to further assess client goals and expectations through contracting. As a part of this process, the counselor can assess the client's

willingness to participate in genetic counseling. Whereas some individuals are eager to take part, others are resistant or reluctant (30). Resistant clients are not completely invested in genetic counseling services. They may feel as if they were pushed into genetic counseling (by a health care provider or a family member), may not completely understand the reason for referral, may be scared about what they will find out, or may see the genetic counselor as a gatekeeper of, and hence impediment to, something they want such as genetic testing. They may show their resentment or may refuse to take part in important aspects of the genetic counseling process such as agenda setting or providing complete family history information. However, at some level, they are willing to be present at the session. Reluctant clients have been distinguished from resistant ones in that they do not want to take part in genetic counseling at all (30). Since resistance or reluctance can impede the work of genetic counseling, identifying and addressing these client characteristics is an important early component of psychosocial assessment.

A key component of the psychosocial assessment process is ascertaining the client or family's knowledge and experiences related to the condition or risk in question. An effective way to collect this information is by eliciting their story. Determining how the client learned about the genetic condition or genetic risk, what he or she knows and has been told about it, how serious he or she views it to be, and how he or she has managed the condition or risk in the past helps the counselor begin to understand the potential impact of genetic information. If the client is affected with a condition, obtaining his or her personal story, from first learning about risk through diagnosis, treatment, and follow-up, is important. Information gathered as part of the family history, including who has been affected, how they were diagnosed, the severity of the condition in these individuals, and who is thought to be affected (even without an established diagnosis) is another source of psychosocial information. Through hearing the story, attending to nonverbal messages, using open-ended questioning, and using primary empathy, the counselor is often able to identify the client's emotional and cognitive reactions to the genetic condition or risk. Identifying whether the client's views are similar or dissimilar to those of their spouse, family, cultural group, religious group, or other possible sources of support is another important component of the assessment process.

Some clients may be hesitant to share their story out of fear of having a strong emotional reaction, concerns about confidentiality, or because of feelings of distrust, guilt or shame. Alternatively, hesitance may be a function of not understanding the scope of the genetic counseling process. It is contingent on the counselor to demonstrate his or her willingness to fully explore the client's experience. In addition, demonstrating unconditional positive regard, empathy, and genuineness (Carl Rogers' facilitative conditions) can help the counselor develop rapport, build trust, and promote client disclosure.

**21.2.2.2 Psychosocial Assessment of Defenses.** Part of the psychosocial assessment process can involve identifying a client's defense mechanisms and coping strategies. Defense mechanisms are a person's way of trying to dampen the emotional effects and maintain control of a potentially threatening situation. They can provide the client with a temporary way of distancing him/herself from the full impact of the situation while he/she (ideally) garners his/her resources to cope with it in a more effective way. McCarthy Veach, LeRoy and Bartels identified nine different defense mechanisms that may be encountered in genetic counseling: denial, displacement, identification, intellectualization, projection, rationalization, regression, repression, and undoing (30).

Coping strategies are the way that people approach to solving a problem or dealing with a difficult situation. Djurdinovic identified eight coping strategies in genetic counseling clients: confrontative, distancing, self-controlling, escape-avoidance, accept responsibility, seek social support, plan, and positive reappraisal (31). Whereas the first five function more as defense mechanisms, clients who seek support, plan, or use positive appraisal are more likely to adapt positively to the situation. Recognizing where the client is in the process of adapting to genetic information, the short-term value of defense mechanisms at points in the process, and when it is important to encourage clients to seek more productive ways of coping is an important part of promoting adaptation.

**21.2.2.3 Psychosocial Assessment and Cultural Competency.** A client or family's cultural identification can have an effect on how they view a genetic condition or risk and how they participate in genetic counseling. Culture has been defined as the beliefs, behaviors, attitudes, values and expectations held by a social group (32). Ethnicity has been defined as membership in such a group based on shared kinship, language, experience, and/or religion (32). Culture goes beyond race or ethnicity to include other social groups such as the Deaf community or the intellectual disability community. In genetic counseling, culture and ethnicity can have an impact on beliefs about causality, the social implications of a condition, and acceptable ways to manage genetic risk. It can also have an impact on expectations and perceptions of genetic counseling, communication within the family and with health care providers, and views and practices related to health, illness, disability, marriage, and reproduction. For these reasons, identifying whether a client identifies with a particular cultural group and then managing the genetic counseling session in a culturally sensitive way should be part of the psychosocial assessment and counseling process. This requires that the provider strive for cultural competence.

Cultural competence is the ability to recognize the impact of a client's culture on perceptions, beliefs, attitudes and values and then to effectively tailor services in response to these cultural considerations. Three major

components of cultural competence in health care have been described: knowledge of the culture, the skills to work with clients from different cultures, and awareness of one's own culture and the potential biases it imposes (32). In genetic counseling, knowledge should extend to factors such as racism and history of persecution, both of which can have an impact on the counselor's ability to build a trusting relationship with clients. Recognizing different decision-making styles and who has the authority to make decisions is particularly important. So is identifying the value that the client/family places on individual autonomy versus collectivism or familism.

Skills include being able to use culturally sensitive communication approaches based on awareness of factors such as proxemics, client's use of eye contact when speaking and listening, and the appropriateness of touch (for example, hand shaking). Being able to navigate differences between a client's culturally determined beliefs about causality and biomedical explanations is another necessary skill. Recognizing and responding to differences in how emotions are expressed and receptiveness to answering routine (but potentially sensitive) questions are two additional skills a counselor should cultivate in striving for cultural competence. It is important to keep in mind that immigrants from any country are highly diverse, often representing many ethnic, religious, socioeconomic, or linguistic groups, and varying levels of education and medical sophistication. Thinking that all people of a specific ethnicity are the same can impede the work of genetic counseling. Knowledge of a culture should serve as a jumping-off point for assessing a client or family's beliefs and values. Having a way to assess the impact of acculturation on a family's cultural identity is particularly important to prevent stereotyping.

Language barriers can significantly influence the quality of communication in genetic counseling sessions. Having access to skilled interpreters can enhance communication between health care providers and clients who speak a different language. However, access is not always available. Although sometimes unavoidable, using a family member—especially a child—or expecting one member of a couple to translate for the other can compromise the interaction. It can create awkward situations when sensitive information must be obtained or discussed. In addition, the relative may choose to share only a subset of the information provided by the counselor, thus jeopardizing informed consent. Ideally, the genetic counselor should cultivate relationships with one or more professional medical interpreters and familiarize them with the goals and processes of genetic counseling. Asking an interpreter about relevant cultural issues can also help the counselor identify appropriate strategies for working with a client.

The third component of cultural competency is awareness. All genetics providers should be aware that they have their own cultural views and that these views may have a conscious or subconscious effect on genetic

counseling interactions. These views may be related to ethnicity and/or religion but also to being a health care professional. For instance, by virtue of the services they provide, prenatal genetic counselors believe in the value of prenatal screening and diagnosis. Cancer genetic counselors believe in the value of risk identification, screening and prevention. These values may not be shared by a subset of reproductive genetics or cancer genetics clients. The counselor should also strive to recognize her attitudes regarding individuals from various cultural groups and assess the validity of these attitudes and their impact on genetic counseling. Finally, the counselor should be aware of cultural biases that are built into the health care system and, when possible, work to address those that prevent culturally different clients from having access to services.

In summary, culture and ethnicity can have a significant influence on all aspects of the genetic counseling process. As client bases become more ethnically diverse, it is even more critical for genetic health care providers to recognize and address this influence in a culturally sensitive way. As such, assessing the impact of culture and ethnicity is a necessary component of the psychosocial assessment.

**21.2.2.4 Psychosocial Counseling and Support.** As delineated in the genetic counseling practice analysis (27), counseling and support, as it is currently practiced, involves addressing clients' emotions and behaviors, using reframing to help them think about a problem in a different way, using knowledge gained during the psychosocial assessment to provide anticipatory guidance, helping them recognize that they have the ability and authority to make their own decisions (within their cultural framework), and facilitating decision making, communication within the family, and adjustment. Different techniques adapted from various theoretical approaches are used to accomplish these counseling objectives. The sections below provide additional detail about elements of this process.

**21.2.2.5 Addressing Client Emotional and Cognitive Responses.** Referral for genetic services can trigger a number of emotional and cognitive responses, which unless acknowledged and addressed, can block the work (e.g. education, informed decision making, coping) of genetic counseling. Communications skills such as attending, empathy, and open-ended questioning serve a number of functions. The counselor can use these skills to bring clients' emotions and thoughts out in the open, to give them permission to discuss their reactions, and to build rapport and establish a trusting relationship. Use of such skills can help the counselor determine when a surface reaction, such as anger, might be masking a different feeling, such as fear, the approaches to managing which would be different. A counselor can also determine the intensity of the client's emotional reaction (e.g. concern versus despair) and context in which the reaction is occurring. For instance, many clients who are referred for positive maternal serum screen results are anxious,

but the level of and source of anxiety can vary. Some are mildly anxious and others are overwrought. For some, the anxiety comes because the result was unexpected, whereas for others, it is because they are under the misconception that the baby has already been diagnosed with the condition. In contrast, others may be more anxious about the possibility of having a diagnostic procedure. Through skilled use of communication techniques, the genetic counselor can assess the quality of and primary reasons for clients' reactions and address it accordingly.

Two client reactions that are prevalent in genetics services and warrant special consideration are guilt and shame. Guilt is feeling responsible for a situation, i.e. not meeting one's own standards or living up to one's own expectations. The typical defense mechanisms associated with guilt include trying to forget the source of one's bad feelings (repression), finding somewhere else to place blame for the situation (intellectualization) or trying to consider the positive aspects of it (rationalization) to reduce personal responsibility (33). All of these serve to reduce a person's self-recriminations. In contrast, shame is the feeling that a person is not meeting someone else's standards or societal expectations. With shame, the defense mechanisms often serve to reduce the cause of a person's loss of self-esteem through denial, relabeling a loss as a gain (reaction formation), compensating or overcompensating in some other area (for instance, being the "best" parent to an affected child), or highlighting others faults to diminish attention on one's own (33).

Because the psychological implications of guilt and shame are different, they require different counseling interventions. In both cases, the process starts by providing the client with an environment where she can openly admit her feelings (confession of guilt or shame). Then interventions that use authority, normalization, reframing (thinking about responsibility in a different way), or limiting liability can be used for addressing guilt reactions (33). Those that seek to develop a nonjudgmental working alliance promote sharing of feelings, highlight the positive aspects of the client, and bolster her ego are more appropriate for shame (33). Being able to distinguish between guilt and shame and use the related counseling interventions is thus important in managing these reactions effectively. Simply telling someone that it is not their fault without further exploration is probably not effective and represents a missed opportunity to help manage what can be significant reactions.

**21.2.2.6 Reframing.** Sometimes, clients are not fully aware of their emotional or cognitive reactions. For instance, a client may not realize that her fear of amniocentesis is more related to the potential results of the test than the procedure itself. Or, sometimes, clients need help thinking about their genetic risk or condition in a different way. For example, a woman presenting for cancer genetic risk assessment and testing may think that inheriting the mutation in her family means she will die of breast cancer similar to her mother rather than seeing

it as an opportunity to reduce her chance of this outcome. In these situations, the tasks of the genetic counselor are to generate ideas about potential gaps in the client's awareness and then fill in these gaps with the goal of broadening the client's perspective (reframing or advanced empathy).

Reframing can bring unrecognized emotions to the surface or challenge longstanding beliefs. Therefore, counselors need to have built rapport and established trust before using this technique. An advanced empathy statement should be clear, specific, nonjudgmental, and suitable for the client. It should also be tentative, so that the client has a chance to agree or disagree with all or parts of the message (30). Reframing is not used as often as other techniques in genetic counseling. However, when used appropriately it can enhance a client's insight. This in turn could result in more informed decision making and/or better adaptation to genetic information or risk.

**21.2.2.7 Facilitating Decision Making and Promoting Adaptation.** Genetic counseling clients are faced with a lot of different decisions. These include whether to have carrier testing to learn about reproductive risk; whether to have prenatal diagnosis for a genetic condition; whether to continue, terminate, or place for adoption an affected pregnancy; whether to use assisted reproductive technology (ART) to prevent the conception of an affected pregnancy; whether to have a diagnostic test or have a child tested; and whether to have presymptomatic or predictive genetic testing. In such situations, the goal of genetic counseling is to ensure that the client makes an informed decision, without coercion, that is consistent with his/his family or community's values and beliefs and is in his/their best interests.

What is the role of the clinician in these types of decisions? Traditionally, in genetic counseling, the role has been to provide the information about the conditions to facilitate informed decision making. The clinician outlines the potential decisions to be made and provides unbiased (ideally) information about each, so that client can make his own decision. Additionally, some clinicians may explore the client's perceptions regarding the benefits, risks, or limitations of each decision as part of the decision-making process. However, in keeping in line with the nondirective roots of genetic counseling, clinicians typically have not shared their own impressions about which decision is best. An exception is made, though, when the decision involves medical care such as screening recommendations for a preventable adult-onset condition such as cancer or cardiovascular disease.

What is the role of the client? The client is expected to use the information in genetic counseling to make the best possible decision for the given situation. However, despite the value genetics professionals place in a planful (rational) decision-making style, this is only one of the possible ways a client may approach a decision. Other decision-making styles include intuitive, agonizing, delaying, impulsive,

fatalistic, compliant, and paralytic (30). Although these styles make work in some situations, they are often not ideal when a client is faced with making a decision that has significant long-term consequences. Moreover, there can be factors that affect the client's willingness or ability to use the information presented to formulate a decision. These can include factors specific to the client such as educational level, motivations to learn about genetic risk, and perception of disease severity. They can also include factors specific to the clinician such as willingness to provide information in an understandable way, supportiveness, and awareness of relevant cultural factors. For these reasons, it is incumbent on the clinician to carefully assess the quality of the decisions clients are making and to work further with clients when the quality is in question. The goal is not to impose the clinician's decision on the client but to make sure the client's decision is as well informed by his circumstances as possible.

Whereas many genetic counseling clients, once presented with the needed information, are able to make a decision, others may become overwhelmed by the process. In such cases, using a rational decision-making model (30) may help the clinician facilitate decision making. In this model, the clinician works with the client to lay out all the possible decisions that can be made (options) and to list the relevant factors associated with each option. Relevant factors can include but are not limited to medical facts, financial issues, cultural influences, and emotional or cognitive reactions. Once all the options and factors have been listed, the client can determine which option is the best based on which one includes the most important of his relevant factors. This model provides clients with a systematic way to identify which factors they value the most and which decisions are most affected by these factors. It also helps clinicians better understand the context in which the decision is being made.

### 21.2.3 Risk Communication and Assessment

Genetic counseling involves the calculation and communication of numerous risks and risk factors. Accurate risk and recurrence risk assessment are viewed as critical for clients to make informed choices about reproduction, pregnancy management, health screening and surveillance. There are many nuances related to the communication of risk or probabilities of an event in the context of the clinical setting and client's worldview.

Jehannine Austin suggests that:

*"... we tend to use the word "risk" as a synonym for "probability"... what we are actually measuring and discussing is not the accuracy of our clients' risk perception, but rather the relationship between our clients' subjective perception of numeric probability and the objective numeric probability of a given outcome." (34)*

This quote highlights that while numbers, facts and figures are useful decision-making tools for many health care practitioners and some clients, they may also be confusing and at times irrelevant to a client whose views are shaded by their personal experiences with the condition and own perception of a "high" risk or a "low" risk (35). Furthermore, the concepts of percentages and probabilities are difficult concepts to explain and for many people to apply in a meaningful way when making a health care decision. There is a growing body of literature that examines the role of risk communication in the genetic counseling process and its effectiveness. In many cases, clients are unable to accurately recall the risks provided by the health care provider or may be confused by the implications of the risk provided (34,36).

A client's subjective risk perception may vary significantly from the objective risk provided oftentimes because of their personal context. An individual's context is defined by the client's personal experience with a condition, their perception of the severity of the condition, their knowledge of the disorder and the perceived impact that the disease or condition will have on them and their family. Many clients' views are shaded by having taken care of a family member affected with a particular condition, the loss of loved ones to a genetic disorder and concern for their own children or other family members if they themselves were to become sick or disabled. This information is utilized by the client to establish their personal concept of risk in context of their life before a genetic counseling session. It may be helpful to ask the client early in the session what their perceived risk is for a particular event and how they have determined their risk. This will allow the counselor insight into the contextual considerations of the client that may cause them to under- or overestimate their risk. For example, two sisters whose mother is BRCA positive have the same objective risk to be a carrier. However, one woman may perceive her risk to be higher than her sister's risk because she looks or acts similar to her mother. In this case, the objective risk assessment is modified by the client's "likeness" to her mother in appearance and personality that is actually irrelevant to her Mendelian risk of 50% to be a carrier.

Genetic counselors strive to present risk in a nondirective, value neutral manner that allows a client to utilize the information for informed decision making. As previously mentioned, numerical information is difficult for many people to evaluate and compare. Table 21-4 lists several evidence-based principles for effectively providing risk information. Risk may be presented to a client in numerical terms such as probabilities, percentages and frequencies or in verbal terms such as "high," "very high" or "minimal." Visual aids such as bar graphs and pie charts can be utilized to explain risk in a visual manner. Verbal descriptors are very subjective in value and should be minimized in order to prevent the counselor or provider's personal risk perception from unduly influencing the client's perception of the risk (34).

**TABLE 21-4** Principles for Effective Communication of Risk Information

- Use of ratios (e.g. 4 in 1000) not proportions (e.g. 1 in 250) when comparing risk
- Use of frequencies not percentages for single event probabilities
- Avoid using percentages if they indicate a chance of less than one (e.g. 0.15%)
- Round up percentages (i.e. do not use decimals)
- Avoid explaining risks in purely verbal terms (such as “low risk”) because of the vagueness and directive nature: elaborate by providing numbers
- Use similar presentations when comparing the chances of different outcomes (e.g. do not use “50%” for risk A and “4 in 100” for risk B)
- Use the same denominator when comparing risks (e.g. do not use “1 in 100” for risk A and “1 in 10” for risk B)
- Present absolute risks alongside relative risks
- Offer outcomes in both a negative (undesired) and positive (desired) framing (e.g. risk of having an affected child versus risk of not having an affected child)

Adapted from Henneman et al. (83).

Framing of risk can be a powerful way of presenting risk information. Framing of risk involves the presentation of an outcome in a positive or negative manner. A risk that is framed in a negative sense reports the chance of an adverse outcome such as 60–80% chance of breast cancer. A risk framed in a positive context highlights the likelihood that an adverse outcome will not happen; a 20–40% chance of not developing breast cancer. One cannot assume that a client will be able to determine the positive frame if only the negative frame is provided or vice versa; therefore, it is valuable to explain risk in the terms of a positive and negative frame.

Checking a client’s understanding of the risk information that is provided in the session by giving them the opportunity to ask questions or repeat the information back can help in determining if the client has understood the information provided.

Risk communication is dependent on accurate and individualized risk assessment. Some of the most challenging risks are the ones that a genetic counselor or geneticists must calculate to incorporate one or more factors that will modify a person’s genetic risk for a condition. Because of this, accurate risk calculation is at times a complex process that some individuals may find daunting. It is recommended that any multipart risk calculation be reviewed by other team members to ensure the accuracy of the calculation and that all considerations have been included (37). A more detailed discussion of this topic is included at the end of this chapter.

## 21.2.4 Client Education

Genetic education is an ongoing piece of the genetic counseling and can be found in every step of the process. The

importance of education is highlighted in the definition of the profession, “Education about inheritance, testing, management, prevention, resources and research.” (6). It is positioned between the medical interpretation portion of the definition and the counseling portion of the definition, which signifies the value of education to bind the genetic assessment to the usefulness and assimilation of the information into the client’s worldview. In many ways, a correct diagnosis or risk assessment is of little value to a client if it is not provided in a way that allows the client to derive personal meaning from the information. It is also important to consider that the manner in which the client education piece of the genetic counseling experience is provided because it can influence the reaction and adjustment of the client to the information.

Genetic counselors must consider numerous variables when providing education to a client. They must quickly assess an individual client’s educational background, cognitive abilities, learning style, prior knowledge of the condition, and personal experience with the condition. Each of these factors will shape the type of information that a client would like to know about the clinical diagnosis and the best way for an individual to receive and assimilate this information (38). Psychological factors such as grief, stress, and depression can also influence the reception and interpretation of the educational component of the genetic counseling process. In many situations, genetic counselors are also obligated to provide education on topics such as pregnancy termination or genetic discrimination that a client may be resistant to hearing about or completely unaware.

The public’s general awareness of genetics continues to increase because of the immense amount of information available on the Internet to anyone with access to a computer. The available information includes both primary scientific literature and individual accounts of a genetic condition, some of which is reputable and some of which is not. As a result, many genetic counseling clients have done a significant amount of self-education about genetics; however, there also exists a client population that presents with very limited knowledge of genetics. This challenges the counselor to be well versed in explaining genetic information to anyone along a wide continuum of knowledge and experience.

## 21.2.5 Genetic Testing and Screening

Genetic testing may be recommended as a part of genetic evaluation or a client may seek genetic counseling about the result of a screening or diagnostic genetic test that was ordered by another health care provider. There are many different types of genetic tests available and they each serve a distinct role in the evaluation of an individual for an inherited condition or predisposition to an inherited condition.

The specific application of a diagnostic clinical genetic test is dependent on the client’s needs. When there is a

known or suspected genetic condition in an individual, the diagnostic test is used to confirm or rule out the condition in an individual with clinical symptoms of the disorder. A presymptomatic or predictive test is utilized in an asymptomatic individual with a family history of a genetic disorder. In this case, a positive test would confirm the condition in the individual and a negative test would exclude it.

Clinical genetic testing is ordered in the health care setting by a qualified health care provider and the results are included in the client's medical record. Laboratories that provide clinical testing must meet the standards for quality and proficiency established by the Clinical Laboratory Improvement Act/Amendment (CLIA) (14). GeneTests, which has recently been redesigned and renamed the Genetic Testing Registry, is a database hosted by the National Center for Biotechnology Information (NCBI), which provides a voluntary, but fairly comprehensive, searchable listing of clinical and research genetic testing.

Genetic screening is offered in several settings to identify genetic disease or risk for disease in the general population or in specific high-risk ethnic groups. Some screening tests do not test the specific gene/genetic defect responsible for a condition; instead, they test for other analytes that suggest the disease and then the individual is referred for additional diagnostic testing. Or, a screening test may only analyze a portion of commonly known disease-causing alleles as in general population screening for cystic fibrosis. Screening tests are generally not as sensitive or specific as diagnostic tests and clients should be fully informed of the limitations of a screening test.

Newborn screening is another application of genetic screening for rare, but oftentimes catastrophic conditions on a population level. In this situation, newborns are determined to be at risk for certain hereditary inborn errors of metabolism and other genetic or not genetic disorders that can require intervention in the newborn period. Further diagnostic testing can proceed while the infant is being treated for the disorder and hopefully avoid many of the devastating effects of the disease.

Prenatal testing can include both screening and diagnostic testing. In this setting, maternal serum screening and invasive diagnostic testing should be available to all women, regardless of age, for chromosome aneuploidies (39). Maternal serum Alpha-fetoprotein (AFP) screening is used to identify pregnancies that may have an open neural tube defect. The screening test identifies a cohort of women that are at a relative increased risk for these conditions. These women receive additional counseling and are offered a prenatal diagnostic procedure to confirm or exclude the potential condition in the fetus. Prenatal diagnosis and preimplantation diagnosis (PGD) can be utilized by clients with a history of a known genetic condition or for common aneuploidies to identify a fetus or embryos affected with the familial condition or aneuploidy.

For some syndromes and conditions, there may not be a clinical test available and one must consider research

testing options. Research tests are usually done as part of a study (e.g. gene mapping or disease characterization) or when the lab is in the investigational stage of developing a clinical test. Research testing is conducted under institutional review board-approved protocols that usually specify that participants will not be given their results and any results obtained should not be used for clinical management. In order to use these results for management, they must be replicated in a CLIA approved laboratory.

The genetic counselor is often responsible for investigating testing options and identifying the most appropriate testing laboratory for the individual client. In addition to the above mentioned issues to consider when selecting a test, one must also consider several other factors. The methodology to evaluate a specific gene can be very different between laboratories and certain strategies are more appropriate for some clients than others. A laboratory must be selected based on the use of the best methodology for the particular client. Cost and insurance coverage for a test are also a consideration when ordering for genetic testing. Genetic testing can range from a few hundred of dollars to thousands of dollars. Third party payers such as Medicare, Medicaid and private insurance have very specific policies about the circumstances in which they will pay for testing and for what portion of the cost of the test they will pay. Additionally, there may be requirements that a certain laboratory be utilized for specific testing.

Many times, a genetic counselor will write a Letter of Medical Necessity (LMN) on behalf of the client to determine if a test will be paid for by the insurance company and to obtain preauthorization if needed for a test. Within the letter, there should be information about the indication for testing, application of the results, and the CPT (Current Procedural Terminology) codes used for billing. The turnaround time for test results and sample requirements, are also important considerations to ensure that the testing can be completed on the sample available and in a time frame that meets the clients needs.

Pretest counseling before any genetic screening or diagnostic test should include a complete disclosure of the potential risk, benefits and limitations of the genetic testing and screening. The counselor should be prepared to discuss the testing methodology, clinical utility, costs, expected results and possible unexpected results such as variants of unknown significance, unanticipated results (e.g., identification of a risk for adult onset disease in a child having whole exome sequencing for pediatric indication), or false paternity and any other issues raised by the client before testing. In addition to technical issues related to the test, pretest counseling should include a broader discussion of the potential for genetic discrimination in the context of insurance coverage or employment. Providers should be well versed in both federal and state legislation regarding genetic discrimination in order to provide clients with a full disclosure of additional implications of genetic testing. As part of the pretest

counseling session, any required laboratory or institutional informed consent documentation for the testing should be reviewed and completed. Clinicians should also be aware of any state legislation requiring informed consent and comply with such regulations. Some clients will participate in pretest counseling and elect to decline the testing or procedure. In this case, the client's decision should be supported and the reasons for the client's decision should be documented as part of the medical record.

Posttest counseling may be in the form of a brief phone call to let the client know that a result was normal and to answer any additional questions or it may be a part of an additional counseling session. During a posttest counseling session, a client is typically provided a full disclosure of the results as well as the implications of a positive, negative and a variant of uncertain significance to the individual. Some exceptions may be made with whole exome sequencing where clients may be given the option of different levels of disclosure or some information may be withheld depending on the nature of the genetic risks identified. Ideally, posttest counseling is done in person in order for the provider to have a significant amount of time to discuss the result and gauge the client's understanding based on verbal and nonverbal communication. However, this is not always possible because of a multitude of issues including the client's access to the clinical setting, missing time from school or work or scheduling conflicts.

Direct to consumer (DTC) genetic testing is now available from numerous private companies to anyone that would like to submit a sample and a payment for the test. This testing falls outside of the traditional medical model and has the potential to increase access to genetic testing for virtually anyone. The purchaser receives an evaluation of their genome with information about pharmacogenetics, carrier status of certain conditions and relative risks for some common disease. Genetic counseling may or may not be available from the company that provides the test. Currently, there are limited regulations of companies that provide DTC testing (40). Several studies have been done to assess how consumers respond to this information (41,42). It remains unclear at this time how testing ordered outside of the medical model can be integrated in to our current medical record system. A study of the NSGC membership revealed that genetic counselors have had few requests for counseling related to the results obtained from DTC testing and that they would consider recommending DTC testing in certain clinical scenarios (43).

### 21.2.6 Follow-up

At the conclusion of a genetic evaluation or genetic counseling session, it is important to develop a mutually agreed upon follow-up plan with the client. The follow-up plan should include documentation of the encounter to the referring physician and all specialists involved in the client's care, documentation of the visit in the medical record and ideally written communication back to the

client that summarizes the evaluation and management plan. The genetic counselor is oftentimes also responsible for coordinating any testing recommended during the evaluation, for developing a plan with the client regarding results disclosure, for scheduling any recommended referrals to other specialists, and for coordinating return appointments to the genetics center as needed.

The follow-up communication with the referring physician, specialists and the client serves as a way to ensure that outcome of the genetic evaluation is available for future use. These communications may take the form of dictations to the client's medical record, letters to a referring physician or a "patient letter" that summarizes the genetics assessment and counseling in laymen's terms. Medical dictations and letters to a referring physician may also be reviewed by the client's insurance company to justify the billing and reimbursement for a genetics visit and justification for genetic testing that was recommended during the consultation. It is important that the letter or note captures the full breadth of the evaluation, the level of service, the counseling provided to the client and the follow-up plan. These documents may also serve as an educational tool to provide a referring physician and future physicians with information about diagnosis that is important for an individual's health management plan. For example, a letter or note for a woman that has been evaluated for a family history of breast cancer could include her family history of cancer, personal medical history, genetic risk assessment to be a *BRCA 1* or *2* gene carrier, a brief description of hereditary breast and ovarian cancer syndrome, recommendations for testing for the *BRCA 1* and *2* genes, suggestions regarding appropriate breast and ovarian cancer surveillance should she have a positive or negative test, the client's desires for testing and surveillance at the time of the appointment, and/or recommendations for testing of other family members. This information would then help the client's referring physician manage the client's health surveillance plan to best address her potential increased risk for breast and ovarian cancer. It could also be used to help support the need for genetic testing to her insurance company when requesting payment for the test.

Many centers send client letters at the conclusion of the genetic evaluation and counseling to summarize historical data and test results that were relevant to the diagnosis and to review the information about etiology, prognosis, or genetic risk that was provided. Such a letter gives clients a record of the consultation that they can retain as part of their personal medical information and may make it easier for them to share relevant findings with other family members and future health care providers. The letter may also include information about support groups, advocacy groups and other psychosocial resources that the client may find helpful based on their particular situation.

Letters to the client can also provide an additional opportunity to identify any misperceptions that the client may have had during the evaluation and to emphasize the importance of seeking another consultation should their

family situation or reproductive plans change. If there is no intention to see the family back, the letter should point out that because of rapid advances in medical genetics, which may affect future methods of diagnosis or treatment, the family may wish to stay abreast of progress relevant to their condition via newsletters from advocacy groups, online resources, and/or by recontacting the genetics center if they have questions. The client can also be encouraged to recontact the center if there are changes in the family history such as new babies born with a birth defect or a family member diagnosed with cancer that might influence the client's genetic risk assessment. If a client letter is not provided to the client, a copy of the dictation or letter to the referring physician can be sent to the client for their records. While these documents may have language that is unfamiliar to the client, it will provide them with a record of their evaluation that they can share with others as needed.

### 21.2.7 Genetic Counseling Across the Lifespan

Genetics and genetic factors influence human growth and development from before our conception until our ultimate death. The scientific communities' ability to identify and test for contributing genetic factors has significantly increased with advances in genetic technology. In some cases, the advances in technology have proceeded faster than the ability to incorporate them into the current medical practice models. Below is a description of common indications for genetic counseling throughout the life-cycle and the counseling considerations for each as well as possible future directions. As it is impossible to capture the full scope of any single area of genetic counseling within this chapter, readers are encouraged to review other chapters within this text and outside resources that have more in-depth reviews of many of these topics.

### 21.2.8 Reproductive Genetic Counseling Overview

Reproductive genetics includes not only prenatal screening and diagnosis but also encompasses preconception genetic counseling, Assisted Reproductive Technologies (ART) and preimplantation genetic diagnosis (PGD). Information about prenatal diagnosis should also be considered in almost any genetic counseling situation, as many clients are interested in learning about the chance of passing on a particular condition to their children. Therefore, it is important to be aware of the reproductive options currently available for genetic conditions regardless of an individuals' practice area.

According to the 2010 National Society of Genetic Counseling's Professional Status Survey, 32% genetic counselors provide prenatal counseling (44). This represents the largest single practice area for genetic counselors. Initially, much of the growth in demand for genetic counseling services came with the dawn of prenatal

diagnosis in the late 1960s and early 1970s. At that time, women were referred for prenatal diagnosis via an amniocentesis because of the increased risk for chromosomal trisomies associated with advanced maternal age or because of a risk of a specific genetic condition due to a history of a previously affected child or family member. Testing at that time was limited to the identification of large structural cytogenetic abnormalities and aneuploidies and testing for a few single-gene disorders. Now prenatal testing, and in many cases, preimplantation genetic diagnosis is possible for most single-gene disorders in which there is a known mutation. Enhanced cytogenetic testing with florescence in situ hybridization (FISH) and array comparative genomic hybridization (aCGH) is also being utilized and developed for prenatal diagnosis to identify small gains and losses of genetic as well as the large cytogenetic abnormalities (45).

Owing to the advances in maternal serum screening and prenatal ultrasound, a greater number of pregnancies at risk for neural tube defects, Trisomy 21 and 18 are identified by noninvasive measures. There have also been changes in current standard of care that now make these screening tests and diagnostic tests (amniocentesis, chorionic villus sampling (CVS)) available to all women, regardless of age (39). The improvements in the sensitivity of noninvasive prenatal screening, and possibly society's changing and more inclusive view of individuals with disabilities, have resulted in a significant decrease in the utilization of prenatal diagnostic procedures since the mid-1990s (46). Emerging directions in prenatal screening include the utilization of noninvasive prenatal diagnosis utilizing fetal DNA analysis from maternal serum may. This may further impact the use of the traditional prenatal diagnostic procedures of CVS and amniocentesis (47).

### 21.2.9 Preconception Genetic Counseling

Women and couples are referred or seek genetic counseling before pregnancy for numerous reasons, some of which are listed in Table 21-5. This is an ideal setting for clients to establish a relationship with their genetics provider and fully explore their available options and

**TABLE 21-5 Common Indications for Preconception Genetic Counseling**

- Recurrent pregnancy loss or prior stillborn child
- One parent with a known genetic disease, congenital anomaly or developmental disorder
- Prior child with a known genetic disease, congenital anomaly or developmental disorder
- Family history of genetic disease
- Teratogen exposure (e.g. medications for maternal illness that may put a fetus at risk)
- Ethnic based carrier screening
- Consanguinity
- Infertility

personal feelings about each alternative. These clients benefit from the opportunity to gain accurate information about their individualized risk in future pregnancies, plan any testing that would be needed before a future pregnancy to enable informative genetic diagnosis if desired without being under the pressure and time constraints of an ongoing pregnancy.

Common goals of these sessions are to identify the potential genetic risk factors for the client based on personal, medical and family histories, provide education about the etiology and recurrence risks for the specified condition(s), discuss the prenatal screening and diagnosis options for the specific condition(s), review alternative options such as preimplantation genetic diagnosis, gamete donation or adoption, recommend and facilitate any genetic testing that needs to be done before pregnancy in order to complete prenatal diagnosis, make recommendations to the referring physician for the management of future pregnancies and to provide psychosocial support and resources that could be helpful to the client depending on the indication for the referral.

### 21.2.10 Genetic Applications of ARTs

Assisted reproductive technologies (ART) are available to women and couples that experience infertility in addition to fertile couples that seek out ART as part of PGD for familial single-gene disorders or chromosome conditions such as translocations (Table 21-6). There are a wide variety of ART procedures that range from minimally invasive procedures and hormone stimulation to others that are multistep medical procedures. Artificial insemination and intrauterine insemination deposit a woman's partner's sperm or donor sperm directly into the uterus at the time of optimal fertility. In vitro fertilization (IVF) requires hormonal stimulation of the female to produce oocytes. The oocytes are retrieved and fertilized by sperm in the laboratory. The embryos that are produced divide to a multicell stage and are then returned to the female's uterus for implantation or frozen for use in the future. IVF can be used for male or female infertility and can use the client's gametes or donor gametes. Couples may elect to use donor gametes to reduce their risk for a known single-gene disorder or for women of advanced maternal

age to decrease their aneuploidy risk and to increase the chance of a successful pregnancy. When donor gametes are used because of a known single-gene disorder, it is important to screen the donor for the known condition. When counseling women who have used donor oocytes, the aneuploidy risk to the fetus should be based on the donor's age but not the client's age.

Intracytoplasmic sperm injection (ICSI) is used to address male infertility. Common genetic causes of male infertility are congenital absence of the vas deferens (CBAVD) in men that have cystic fibrosis (CF) or are CF carriers with a 5T allele, Y-chromosome deletions, sex-chromosome disorders such as Klinefelter syndrome (47,XXY) and Kallmann syndrome (48). For this procedure, spermatozoa are retrieved from the testes and a single spermatozoa is selected and manually injected into the oocyte with a micropipette. Couples that elect to undergo this procedure for Y-chromosome deletions and other forms of inherited male infertility should be informed that their male children will also be at risk for future infertility.

Women and couples that are carriers of known autosomal genetic conditions and balanced structural chromosome rearrangements can also consider preimplantation genetic diagnosis. PGD involves IVF combined with genetic testing of the embryos. The embryos that are predicted to be unaffected are returned the uterus for implantation before day 6 or cryopreserved for future use. Women are offered prenatal diagnosis to confirm that the resulting pregnancy is truly unaffected.

Each procedure has its own risks, benefits, limitations and costs. These considerations should be disclosed to clients before proceeding with anyone of these procedures. ART pregnancies have a reported 30% increased risk for birth defects over the general population risk (49). Pregnancies conceived utilizing ART may also have altered second-trimester maternal serum screen results (50). A recent prospective study of children born after PGD and ICSI at 2 years of age did not report any significant difference in their growth development or health between the two groups (51).

### 21.2.11 Indications for Referral and Prenatal Genetic Counseling

Common indications for a prenatal genetic counseling are listed in Table 21-7. Prenatal diagnosis is an option for families with known genetic risk factors such as single-gene disorders and familial chromosome structural anomalies that would increase a couple's chance to have a child with the identified condition. In the 1960s, amniocentesis was introduced and recommended for women of age 35 and older and prenatal screening and diagnosis became a part of routine prenatal care for women, regardless of family history. Genetics in prenatal care has continued to expand to the current recommendations by the American College of Obstetricians and Gynecologists for all women, regardless of age, to be offered prenatal screening

**TABLE 21-6** Indications for Preimplantation Genetic Diagnosis

- Avoiding clinical termination of an abnormal fetus
- Nondisclosure of parental genotype
- Cancer and other adult-onset disorders
- Selecting HLA-compatible embryos
- Mendelian disorders
- Chromosomal rearrangements
- Recurrent pregnancy loss due to aneuploidy
- Aneuploidy testing to improve pregnancy rate

**TABLE 21-7**   **Indications for Prenatal Genetics Referral**

Abnormal first, second, or integrated maternal serum screen
Ultrasound anomaly
Advanced maternal age ( $\geq 35$ at the age of delivery)
Parent with single gene disorder
Both parents are carriers of an autosomal recessive condition
Mother is a carrier of an X-linked recessive condition
Parent with balanced structural chromosome abnormality
Teratogen exposure (e.g. prescription medications, illegal drugs, alcohol, occupational exposure, radiation exposure)
Maternal disease (e.g. diabetes)
Prior child with single-gene disorder
Prior child birth defect or learning disability or mental retardation
Family history of a single-gene disorder
Family history of a learning disability or mental retardation
First trimester serum screening and Nuchal translucency
Ethnic-based carrier screening

for aneuploidies before 20 weeks of pregnancy (39). In addition to maternal serum screening, ethnic-based carrier screening is recommended for women and couples that are pregnant or planning pregnancy. Maternal screening is routinely offered by the client's obstetrician and the client may or may not understand the purpose and limitations of a maternal serum screening test.

Many women are referred for prenatal genetic counseling after they have been informed of an "abnormal" maternal screening result with little additional information about the implications of the result. As a result, these individuals and couples who arrive for prenatal genetic counseling may have a heightened level of concern due to the unexpected potential risk to their unborn child in an otherwise uneventful pregnancy, misconceptions about the reason for their referral and great concern about the possible outcome of their prenatal genetic evaluation. It is important to be mindful of the emotional issues that clients face while they are asked to comprehend the risk figures and procedures that are discussed during their consultation.

### 21.2.12 Overview of the Prenatal Genetic Counseling Process

Many clients are only seen one time for prenatal genetic counseling unless a problem is detected in the fetus. The session is usually before the client's ultrasound, prenatal diagnostic procedure and consultation with a maternal fetal medicine specialists or perinatologist. During the session, the counselor will explain the client's indication for referral, discuss her screening test results or other risk factors, review the mother's medical and prior pregnancy history, obtain and review the family history to identify additional risk factors to the pregnancy, discuss the client's prenatal testing options if indicated, offer population- and ethnic-based carrier screening when appropriate, discuss pregnancy management options if a

problem is discovered or confirmed in the fetus and provide psychosocial support for issues related to concerns about the pregnancy and possible outcomes of testing. For women who elect to undergo genetic testing, the genetic counselor is usually the one who contacts the client with the results. If a client has an affected fetus, the genetic counselor is often responsible for disclosing the results and providing follow-up counseling that includes education about the diagnosis, implications of the diagnosis, resources for more information about the condition or others with the same diagnosis, information about pregnancy management if she chooses to continue the pregnancy and pregnancy termination if she elects this option.

### 21.2.13 Prenatal Diagnostic Procedures

The two most common prenatal diagnostic procedures are CVS and amniocentesis. Both procedures can be used for molecular, cytogenetic and biochemical testing. Both procedures also have associated risks for miscarriage and pregnancy loss.

CVS is offered in the first trimester at 10–13 weeks gestation. During the procedure, a portion of the placenta is obtained by a transabdominal or transcervical approach for genetic testing. The placenta can be utilized because it has the same genetic complement as the fetus. Mosaic chromosome results are more common in a CVS than an amniocentesis and in this case, an amniocentesis in the second trimester may be required. CVS during the first trimester allows many women to undergo prenatal diagnosis before anyone is aware of their pregnancy. It is limited in that it cannot evaluate the fetus for neural tube defects and other structural abnormalities that are not obvious until the second trimester. Therefore, a detailed ultrasound in the second trimester is indicated for women who have undergone CVS as is a second trimester maternal serum alpha fetoprotein (AFP) test to screen for open neural tube defects. The amniocentesis is performed in the second trimester after the fourteenth week. During this transabdominal procedure, a small amount of amniotic fluid is removed and fetal cells are isolated from the fluid for cytogenetic, molecular and biochemical studies if needed. AFP and acetylcholinesterase can also be measured to evaluate the fetus for an open neural tube defect.

Prenatal ultrasound plays an important role in the evaluation of the fetus. Advances in technology allow qualified providers to obtain detailed views of a fetus. Nuchal translucency measurements in the first trimester combined with maternal serum screening results are utilized to improve the detection rate maternal serum screening for fetal aneuploidies. Ultrasound can also routinely identify open neural tube defects, ventral wall defects, some structural changes in the brain and heart, limb defects and overall disorders in growth and development. One challenge presented in counseling clients that have a fetus with one or more ultrasound anomalies with or without a

chromosome disorder is the limited ability to predict the degree of physical impairment the child may experience and, in many cases, the cognitive abilities of the child.

### 21.2.14 Genetic Testing in Prenatal Diagnosis

There are several important points to consider and discuss with clients to assist them in understanding the different options available to them and the potential implications of each option. Counselors should be prepared to discuss each test's diagnostic accuracy for the condition(s) for which they are at risk, further testing that might be needed in the case of inconclusive results, the fetal risk or maternal discomfort associated with each test, timing for testing during pregnancy, turnaround time for results and the expense and insurance coverage for the test. Asking an individual or couple to rank these factors as most and least important can help them choose the option that is best for them. A reflective summary by the counselor of their decision-making process helps to ensure that they have understood and weighed all the various alternatives and their implications.

In clients for whom the primary indication for prenatal diagnosis is the risk of fetal aneuploidy due to an abnormal serum screen, ultrasound findings, or maternal age, an FISH interphase study for the most common aneuploidies (13, 18 and 21) and chromosomes X and Y can be done on the sample. These results are often available 24–48 h after the procedure and can provide some rapid reassurance to many women about their pregnancy. It is important when providing these results to explain that it is only a limited evaluation of the fetal chromosomes and it does not evaluate all chromosomes or the structure of the individual chromosomes. The complete cytogenetic studies are usually available within 2 weeks of the procedure following culturing and full karyotyping.

There is a debate in the current literature and clinical genetics community about the applications of microarray-based aCGH to enhance and possibly replace cytogenetics for prenatal diagnosis. aCGH has the ability to detect copy-number alterations and very small duplications and deletions of genetic information that are not detectable with cytogenetic studies and can have an associated abnormal phenotype. The technology also reveals copy-number variants (CNVs) that may be benign or are of uncertain significance. One limit of this technology is that it does not detect balanced chromosome rearrangements (those that do not result in a net gain or loss of genetic information), which can be seen with conventional cytogenetic studies. These balanced rearrangements can have clinical consequences (52). One of the primary genetic counseling considerations with this technology is how to provide clients with this information during pregnancy in a way that will enable them to utilize it for pregnancy management and not increase anxiety unnecessarily. Van den Veyver et al. (45) reported the clinical use of aCGH in 300 prenatal cases and reported the identification of CNVs in 19.3%

of samples. Forty were classified as likely benign, 15 clinically significant and 3 were of uncertain clinical significance. The authors concluded that this technology did not present major genetic counseling challenges, however, they did not assess the client's perceptions or anxiety related to the results or the genetic counseling provided for the clients.

For women who seek prenatal diagnosis for single-gene disorders, it is prudent to explore the testing options for the condition before proceeding with an invasive procedure. One must consider numerous issues when working with a family that requests prenatal diagnosis for a specific condition. Some considerations are as follows: Has there been informative genetic testing in the family that can be used for prenatal diagnosis? Is there a laboratory that provides prenatal diagnosis for the condition in the family? Can the results be obtained in a timely manner for a client to use them for pregnancy management or termination if desired? What is the cost of the test and the insurance coverage for the testing? Owing to the complexity of arranging prenatal diagnosis for familial conditions, it is prudent for women with a personal or family history of a single-gene disorder that would like prenatal diagnosis to be referred for preconception genetic counseling or early in their pregnancy in order to provide them with as many prenatal options as possible.

### 21.2.15 Population-Based Carrier Screening

Specific genetic conditions such as Tay–Sachs disease and CF are known to be more frequent in certain ethnic populations. The genes for many of these conditions have been identified and carrier screening is now available and recommended on a population basis. Some women will be offered screening in their physician's office and others will be counseled and offered testing as part of a prenatal genetic evaluation. Ethnicity is usually self-reported by the client as part of the medical history. The health care provider should be cautious about assuming an individual's ethnic background based on outward physical appearances.

The American College of Obstetrics and Gynecology (ACOG) and the American College of Medical Genetics (ACMG) have published carrier screening recommendations (53–55). In most cases, clients will have no family history of the conditions for which screening is recommended and limited knowledge, if any, about these conditions. When a woman and/or her partner is identified to be a carrier for a particular condition, the risk to the current pregnancy or future children should be discussed as well as the possibility of prenatal diagnosis for the condition.

### 21.2.16 Communication of Risk in Prenatal Genetic Counseling

A great deal of the informational content of prenatal counseling pertains to risk: the estimated chance that a

fetal condition is present, the likelihood that it can be diagnosed with available techniques, the procedural risks, and the “background” incidence of various problems in the general population. Obviously, these factors are central to decision making, and care must be taken to ensure not only that they are understood but also that their emotional impact is addressed. Just the word “risk” elicits a negative response, and although it is difficult to avoid using it, words such as “chance” or “likelihood” are more emotionally neutral. Talking about background risks can also be alarming; few people embark on a pregnancy with awareness that even without any identifiable risk factors, there is a 3% chance that their baby will have a significant abnormality and a 2% chance that they could lose the pregnancy in the second half of gestation.

Helping clients understand how first- or second-trimester screening changes their chances for certain aneuploidies and neural tube defects can be especially challenging. Many primary care providers do not have a good understanding of the limits of certain maternal serum screening tests and will not be able to answer all of the client’s initial questions about the results. The genetic counselor oftentimes is the first person to have the opportunity to help clients understand that an “abnormal” test result suggests an increased risk for a particular condition and it does not necessarily indicate a fetal abnormality or chromosome disorder.

### 21.2.17 Discussion of Possible Diagnosis in the Fetus

The vast majority of clients who come for prenatal genetic counseling because of an abnormal maternal serum screen are at an increased chance for a specific chromosome aneuploidy or birth defect such as neural tube defect. The genetic counselor or professional working with the client should provide counseling regarding the screening results and should be well versed in the serum screening patterns, fetal and maternal factors that influence serum screen results and the phenotype of each of the possible conditions that can be identified with a maternal screen. The counselor should be able to provide the client with an accurate description of the conditions and the spectrum of the outcomes with each condition. Important things to discuss include any physical or cognitive impairments and special needs a child affected with a particular condition might have, any anticipated delivery considerations such as delivery at a different hospital or surgery after delivery, if a child with a particular condition would be more likely to die in infancy or childhood because of the condition and the genetic basis of the condition. These discussions can be very stressful for an individual or couple and it is essential that a counselor, be mindful of the impact of this discussion can have, anticipates certain reactions to the information such as distress, denial or fear and addresses any obvious psychosocial needs that a client or couple may express.

### 21.2.18 Exploration of Feelings about Testing and Possible Outcomes of Prenatal Diagnosis

At the time of referral, some individuals and couples may unwaveringly state their desire for a particular mode of prenatal diagnosis and their intentions in case of certain outcomes. Others may remain ambivalent and unsure of what to do about testing even after extensive counseling. Clients need to understand from the outset that the role of the counselor is to provide information about the tests and to help them make decisions they are comfortable with. This is particularly important in follow-up of an abnormal screening result, because the urgency of the referral and the anxiety surrounding it may make clients feel as though they have been thrust into a cascade of events over which they have little control. For some clients, the counselor’s nondirective message may not seem to match what they have heard from their primary practitioner. They may say that they are there only because their “doctor said I should have this test” or may even fear that their prenatal care will be jeopardized if they do not follow what they perceive as their prenatal care provider’s recommendation.

It is important that the counseling session not become so focused on the diagnostic methods and the diagnosable conditions that little attention is paid to the reasons for offering testing. Unfortunately, there is still a widespread perception that the sole purpose of prenatal diagnosis is to identify anomalous fetuses, so that their birth can be prevented by pregnancy termination. Other valid reasons that should be reviewed (according to the couple’s situation) are as follows: (1) the likelihood that testing will provide reassurance; (2) the fact that knowing more about the baby’s condition may change how the pregnancy and delivery are managed; (3) the ability to plan for the baby’s treatment in the neonatal period (or in rare cases, prenatally); and (4) the opportunity for the family to adjust, make plans, and marshal resources before the baby’s birth.

Families should also be informed that adoption is another alternative to continuing the pregnancy and caring for the child or pregnancy termination. There are specific adoption services that specialize in the placement of children with special needs with families that have requested the opportunity to adopt and care for a child with special needs.

Before a final decision is made about testing, the counselor should discuss with the client and her partner or support person if available, if they have considered what they would do in the event of an abnormal outcome. Although this is an uncomfortable question for both counselor and counselee, it does acknowledge that they may not be reassured by testing and could face a painful decision as a result. It also provides an opportunity for client to ask about the particulars of pregnancy termination if they wish and gather more information. This is a

good time for the counselor to mention that individuals and couples do not always end up making the decisions they thought they would, to normalize the fact that the wait for test results is always difficult, to invite the client to contact the counselor if they have questions in the interim, and to establish at what time and where they would like to be called with results.

### 21.2.19 Pregnancy Management of a Fetus with an Abnormality

The pregnancy management options that are available to a woman with a fetus with an abnormality or suspected abnormality will vary based on what point during the pregnancy the diagnosis is made. In general, people are offered the option to continue the pregnancy or pregnancy termination. Planned adoption and perinatal palliative care (56) are also options that should be made available when appropriate and available.

For women who elect to continue a pregnancy following the diagnosis of an anomaly or genetic disorder, the general focus of management is optimizing the delivery of the infant and neonatal care. In some cases, a woman will need to transfer her prenatal care to a perinatologist or maternal–fetal medicine specialist, has serial ultrasounds and delivers her baby at a different hospital. If the child will have immediate surgical or medical needs at birth, the family should be given the opportunity to meet with the specialists that will be involved in the neonatal care. The intervening time between the diagnosis and birth is also an important time for the family to plan for the needs of the child, contact support groups and early intervention specialists if needed and prepare their other children, if any, for the additional changes of having a new baby with special needs may bring. Women and couples also begin the active grieving process involved with the loss of the “normal child” and the adaption to the concept of parenting a child with a genetic condition or special needs.

Pregnancy termination options for women are to some degree regulated by state laws regarding the legal gestational age limit for a termination. Providers should be aware of the limits imposed by the state in which they provide care, how the gestational age is calculated and any time constraints that are imposed related to counseling about the termination procedure. In some cases of diagnosis at an advanced gestation age, a woman may have to travel to a different state to receive termination services if they are not legally available in their community.

Pregnancy termination via induction will result in the birth of a stillborn baby. This option provides the opportunity for clinical examination and fetal pathology. Also, additional genetic testing may be possible to determine a diagnosis if one was not established during the pregnancy. This information is very important, especially if a baby had ultrasound anomalies and normal prenatal genetic studies. Information gathered following the

birth of the baby is valuable to provide the parents with answers to why the baby had anomalies and the potential recurrence risk for future pregnancies.

Having an induction procedure also allows for the family to see and hold the baby. While many clients may be hesitant to take advantage of the option, the counselor should discuss with them the unique and limited opportunity that they will have with their baby. At a minimum, pictures should be taken of the baby for the parents to view at a later date. If an anomaly or genetic condition is identified early in a pregnancy, a woman may undergo a dilatation and evacuation (D&E). This procedure does not retain the fetus intact and viewing of the fetus and additional clinical examination will not be possible.

The psychosocial needs for couples who choose pregnancy termination include all of the grief processes that surround a miscarriage, stillbirth or infant loss with the additional feelings of shame and/or guilt for having elected to end a pregnancy (57). There are numerous resources for families that have been faced with this difficult decision that should be provided to the client. An extensive discussion of bereavement counseling is beyond the scope of this chapter, but there are many good resources for this special area of counseling. There is also a growing body of lay literature appropriate for couples that have had a miscarriage, stillbirth, or neonatal death. Numerous local and international support groups exist for parents who have lost a baby. Social services associated with obstetrics and pediatric units can often be of help in identifying resources for patient referral.

### 21.2.20 Pediatric Genetic Counseling Overview

Genetic counseling is provided to families of children with known genetic conditions or at risk for a familial condition, congenital anomalies, dysmorphic features, learning disabilities and mental retardation. ACMG has published recommendations for appropriate indications for referral for a genetic evaluation (58). When families are seen within a genetics center, they often meet with a genetic counselor as well as the medical geneticists. One of the primary goals of a genetics consultation is determining if a child has a genetic condition. Some children have a syndrome that is obvious to the geneticists at the time of the appointment, while in other cases, an etiology, genetic or otherwise, is never determined. It can be challenging to distinguish between environmental, multifactorial and single-gene disorders, which all need to be considered during an evaluation. The accurate diagnosis for a child is essential in order to provide the family with physical, developmental and health expectations for the child and to accurately provide them with recurrence risk for the parents, child and other family members.

Owing to the multisystem involvement of most genetic conditions, families also see a wide variety of other medical specialist, allied health care providers such as

occupational therapist and physical therapists in addition to their pediatrician. They may also interact with numerous educational specialists in order to develop adaptive education plans when needed. Families may ask genetic questions to any member of the health care and educational team, so in a sense, each team member may provide genetic counseling. For this discussion, the focus will be on genetic counseling within the context of the genetics center. Yet, it is important for any professional who works with individuals and families with a genetic condition to become knowledgeable about the genetic etiologies and full spectrum of the condition to better understand the patient or client. Genetics professionals are available for consultation to help all members of the team optimize the care and treatment of individuals with a genetic condition.

### 21.2.21 Overview of the Genetic Counselor in the Pediatric Setting

It is beyond the scope of this chapter to outline in detail the medical evaluation of a child that has been referred for a genetic evaluation; therefore, the emphasis will be on the goals of genetic counseling and the role of the genetic counselor in the evaluation. Other chapters in this book and other resources will provide a full discussion of a genetics medical examination because it is unique in the range of considerations. The genetic counselor plays a central role in the evaluation and care of a child by the genetics team. Many counselors work with medical geneticists or other pediatric specialists such as neurologist and orthopedists that routinely care for children with genetic disease. While the genetic counselor's interaction with the child is very important, it is essential for the counselor to establish a relationship with the parent(s) because he or she will likely interact with the family on numerous occasions. Many children and families are seen on a routine basis of every 6 months, yearly or every 2–3 years to monitor the development of the child.

Before a visit, a genetic counselor may confirm the accurate scheduling of an individual based on indication for referral, collect and review medical records, and contact the family by phone to collect preliminary medical and family history information. During the consultation, the genetic counselor will greet the family and establish the goals and agenda for the visit, collect the medical and family history and explore the family's expectations for the visit. The counselor will then review this information with the medical geneticists or other physician(s) who will see the patient. During the physical exam provided by the physician, the counselor may assist in the exam or assist in the documentation of the exam. The physician will often discuss and educate the family about the diagnosis or differential diagnosis, recommendations for testing, imaging or consultations with other specialists.

The genetic counselor will provide additional education for the family about the information provided by the physician. This may include the inheritance pattern or etiology of a diagnosis, full explanation of any recommended testing including the risks, benefits and limitations of the testing, recurrence risk of the condition for the parents and the child, management guidelines for individuals with specific diagnosis, psychosocial support for issues related to having a child with a medical or genetic condition, identification of resources related to the diagnosis and support groups and the establishment of a plan for follow-up and result disclosure if indicated. Genetic counselors also ensure that the consultation is appropriately documented and billed to the family's insurance company.

Routine follow-up is important in pediatric genetics. A large amount of medical information is provided to a family in the context of an often stressful situation and this can limit the amount of information that can be processed at any one time. Return appointments provide the opportunity to discuss test results and to review information and clarify any misconceptions or questions a family may have. Owing to the rapid advances in genetics, return appointments enable families to be informed of any developments and changes that could be important to their care. Some children are seen during infancy and it may not be until several years later that their diagnosis is obvious based on their growth and development or changes in the family history over time may reveal a diagnosis.

### 21.2.22 Counseling Considerations in a Child with a Birth Defect or Genetic Condition

For many people, the birth of a new baby brings with it their hopes and dreams for the future. Parents name their children, plan their future and set goals for their children before they are even born. These dreams are often devastated when a child is born with a birth defect or genetic disorder. Providing care and counseling for families in this emotionally charged setting can be challenging. In most cases, information about the condition and suspected diagnosis should be shared with the new parents as soon as possible. Some families will be seen in the hospital on the consult service and others will be seen in the office after the child is born. Similar to providing an abnormal prenatal test result, the counselor should be prepared to discuss the diagnosis in detail, including the short- and long-term consequences, assess the parent(s) support and resources, and have plenty of time for the parent(s) to ask questions and process the information and emotional reaction. The counselor should also have written information (pamphlets, websites, suggested lay reading) about the diagnosis or condition at the time of the disclosure to enable them

to identify trusted resources for good information. It is unlikely that the parents will hear all of what is said at the initial appointment or ask all of their questions, therefore, it is important for the counselor to contact the family after the visit to see if they have other questions and to provide contact information to the family, so they can call back or schedule an appointment for additional counseling and education.

One way to assess the couple's support network and their understanding of what they have been told is to ask them with whom they intend to share the information and what they will tell them. It is also important to ask the couple about their other children (if any), for they are sure to sense the parents' distress and may not only be alarmed about the baby but also fearful that something has happened to their mother. The counselor can help the couple decide how much the other children need to know at this point and suggest age-appropriate ways of discussing the baby's problems with them.

With confirmation of the diagnosis, the parents must begin to accept their new reality. This can be accompanied by feelings of responsibility, guilt over real or imagined past misdeeds, anger at the unjustness of the situation, disorientation, and overwhelming sadness. By preparing the couple for these reactions, the counselor can provide reassurance that the emotions are normal and appropriate and that they are not "losing control." They should also be cautioned that two of them may grieve in different ways and at different times and be admonished to keep the lines of communication open.

In later consultations or conversations with a child's parents, the counselor should specifically inquire about how the child's diagnosis has affected other family members, especially the grandparents and siblings, and about how their relationships with each other and with their family and friends have changed. It is also important to find out what lifestyle adjustments they have had to make (childcare, employment, recreation) and to help them differentiate between changes they have made because of the child's condition and those that would have been necessary with any new baby. Referrals to an early intervention program or support group should be made when appropriate. In some cases, one or both members of the couple will not progress in their grieving process, or maladaptive behavior patterns will emerge. At this point, the possibility of individual, marital, or family counseling with another professional should be raised.

Some families are unprepared for the challenges of caring for a child with special needs and need access to alternatives to caring for the child themselves. In these cases, the possibility of placing the child outside of the family, either temporary or permanent, can be raised. Parents should be connected with agencies that can assist with adoption of a child with a handicap or to provide good short- or long-term foster care. For parents who

place their child with an adoptive or foster family, their sense of grief at the loss of their "normal" child can be compounded by their perception that they have also failed in parenting the child. There may be guilt because they see themselves as selfish and the adoptive or foster family as unselfish. The counselor should not minimize the couple's feelings but can remind them of the considerations they took into account in making a decision that they felt was best for them and their child.

### 21.2.23 Evaluation and Counseling for an Older Child or Child with a Chronic Condition

For some children that have a genetic condition it may not be apparent during infancy and it is only when the child fails to meet developmental milestones, develops chronic health problems or has a specific pattern of health problems that the possibility of a genetic condition is addressed. The genetic counselor's role in the evaluation of an older child is very similar to the role of evaluating a newborn or infant but they will have the opportunity to build rapport with the child and the parent(s).

If a child's developmental or health problems have become increasingly apparent over time, much expense and emotional energy may have been devoted to finding a cause, and the family may actually be relieved to have a diagnosis at last. On the other hand, such a diagnosis can bring with it new and distressing information about additional threats that may lie ahead, and in some cases, removes any hope that the child will ever be "well." When a diagnosis such as CF or muscular dystrophy is made, a youngster who has been thought by the family only to have frequent infections, or just to be clumsy and tire easily, now has a known syndrome and the implications for the family as a whole are impacted. The family will understandably be thrown into crisis as they try to learn about the condition and initiate treatment amid fears for what lies ahead—emotionally, socially, and financially. Some families will be expecting another child or already had other children by the time the first child is diagnosed with a genetic condition and are faced with the possibility of having more than one child with a specific condition.

It is perhaps even harder for families to have a possible diagnosis raised without warning. This may occur, for instance, when a pediatrician expresses concern about mild dysmorphism, short stature, delayed development, a suspicious number of café-au-lait spots, or some other finding in a child whom the family perceives as entirely normal. In terms of the family's shock, denial, and anxiety over the implications of the finding, this situation is not unlike having a genetic diagnosis suspected in a newborn and warrants expediting the genetic evaluation and providing the same ongoing counseling. This situation

again raises concerns not only for the child but also for the parents and siblings.

### 21.2.24 Adults with Pediatric Genetic Conditions

An increasing number of individuals with conditions that were previously lethal in childhood are surviving to adulthood. The average life expectancy of a person with CF has increased into the mid-30s (59) and the life expectancy of an individual with Down syndrome is now 60 (60). These individuals face unique challenges in finding “adult” doctors who can help manage their genetic condition as well as other health issues common in adulthood. These adults oftentimes have the same desires for an education, a meaningful employment and a family as other adults. However, they are faced with a chronic inherited health condition that can impact these aspirations. For individuals with significant cognitive impairment, the identification of vocational resources and support services is challenging after they age out of the public education system. As the medical field continues to be successful in increasing the life expectancy for a growing number of persons with previously lethal childhood conditions, it also has to work to meet the needs of this unique adult population.

## 21.3 ADULT-ONSET DISORDERS

While the historical foundation of genetic counseling resides with prenatal and pediatric genetics, it has rapidly expanded into the area of adult-onset disorders. Genetic counseling for adults has been available for many years for certain single-gene genetic syndromes such as Huntington disease and other neurological conditions. Since the mid-1990s, there has been a large expansion into the field of cancer genetics with the discovery of genes responsible for familial breast, ovary, colon and other cancers. Most recently, the genetic counseling field has begun to branch out into the area of multifactorial adult-onset diseases such as cardiovascular disease. Below is a description of genetic counseling services in cancer genetics and adult-onset neurodegenerative disorders (Huntington disease) as two important and representative areas of adult genetics.

### 21.3.1 Counseling Considerations in Adult-Onset Disorders

The adult population that is evaluated for a genetic condition or predisposition to a disease such as cancer has many of the same concerns and needs as those previously addressed, but also some new ones. Many times, individuals who have been healthy their whole lives and have the expectation of good health well into late age are suddenly faced with an unexpected genetic disease

associated with significant morbidity or mortality. Alternatively, the disease may be known in the family and they have assumed that they too will be affected. These individuals may have also had children of their own with or without the knowledge that they had a condition that could be transmitted to them. In this case, there may be competing concerns; concern for their personal health and well-being and the additional concern about the consequences of passing on the condition to their children. This can lead to significant distress as well as difficulty in determining the best course of action with regard to identifying and managing genetic risk.

### 21.3.2 Cancer Genetic Risk Assessment and Counseling

At least 55 genetic syndromes associated with an increased risk of cancer have been described (61). Some are solely associated with elevated risks of cancer and/or benign tumors (e.g. hereditary breast ovarian cancer syndrome), whereas others involve specific physical features in addition to cancer risks (e.g. Beckwith–Wiedemann syndrome). Some are primarily adult-onset disorders (e.g. Lynch syndrome), whereas with others, onset can occur in childhood and/or adulthood (e.g. von Hippel–Lindau syndrome). Clients may be referred to evaluate their chances of having any of these hereditary cancer syndromes. However, the most common indications for referral are to rule out a hereditary breast cancer or hereditary colon cancer syndrome.

Clients are referred for cancer genetics services for a number of reasons including to assess personal cancer risks, to assess risks to other family members, to guide screening recommendations, to make decisions about preventive measures, and/or to have genetic testing to further clarify risks. Some individuals who present for services have already had a cancer diagnosis and others are unaffected. For those who have had cancer, some present at the time of their diagnosis, some are in the middle of adjuvant therapies and others are months or years out from their diagnosis and treatment. Some are healthy, some are in remission, and others are in the terminal stages of cancer. Many clients will have extensive family histories of cancer but a subset will be the first to be diagnosed in the family. The informational and psychological needs and the goals of cancer genetic counseling clients will vary based on these different variables.

Typically, cancer genetic risk assessment begins with a three–four generations family medical history. An accurate family history is critical in assessing whether an individual has an increased risk of developing specific types of cancer and in syndrome identification. Family history is also helpful in determining which other relatives may be at increased risk and in whom genetic testing would be most informative. For those relatives with cancer, the family history should include information about what type of cancer was diagnosed, at what

age the diagnosis was made, how it was diagnosed and treated, the relative's current age or age of death, and whether any relatives have had multiple primary tumors. For those without cancer, current age or age at death and information regarding screening practices should be collected. For both affected and unaffected individuals, information about relevant environmental exposures and prophylactic surgeries should also be gathered. Some syndromes are associated with benign tumors, dysmorphic features, or other medical conditions. When such syndromes are part of the differential diagnosis in the family, appropriate questions targeted to the symptoms of these conditions should be asked of both those affected and unaffected with cancer. Failure to ask such questions can impede accurate syndrome identification.

At times, medical record confirmation of reported cancer diagnoses is important for syndrome identification and risk assessment. For example, Schneider et al. (62) found that cancer diagnoses in hereditary breast ovarian cancer families were more accurately reported than in Li-Fraumeni syndrome families. Whereas relying on verbal reports alone would not have changed recommendations for genetic testing in the hereditary breast ovarian cancer families, underreporting of diagnoses in Li-Fraumeni families would have resulted in fewer than half of the families being offered testing (62).

An accurate family history sets the stage for risk assessment. There are two aspects of risk that are routinely addressed in cancer genetics—an individual's risk of developing cancer and his/her risk of harboring a mutation in a cancer predisposition gene. These risks are estimated by looking for characteristics of hereditary cancer in the family. The characteristics include early age of onset, multiple relatives in a single lineage affected with the same or related cancers, evidence of Mendelian inheritance, individuals with multiple primary cancers or bilateral cancers in paired organs, and/or the presence of rare cancers or benign tumors. On the basis of the presence or absence of these features, a family history can be classified as low (population) risk, moderate risk (probable multifactorial etiology), or high risk (suspected hereditary cancer syndrome).

Risk assessment models that quantify a person's risk of developing cancer are available for some cancers (e.g. breast and ovarian cancer) as are models that estimate mutation probabilities in some genes (e.g. *BRCA1/2*, *MSH2/MLH1*). Clinicians need to be familiar with the limits of these models in order to use them appropriately. In the absence of an existing model, assessing risk involves looking for characteristics of hereditary cancers and symptoms of syndromes that are part of the differential diagnosis in the family history. A physical examination may be part of the risk assessment process when the clinician is trying to rule out a condition with associated physical findings.

Factors including genetic heterogeneity, reduced penetrance, age-related penetrance, variable expressivity, and environmental modifiers (e.g. relatives who have had

prophylactic surgery) can complicate pedigree-based risk assessment. Underreporting of cancer diagnoses, inaccurate reporting and limited family structure can also have an impact. Finally, family history is dynamic and as such, a risk assessment may change over time. Clinicians need to be cognizant of these factors and take them into consideration whenever performing a pedigree-based risk assessment.

Once risks have been estimated, the next step is to communicate them to clients in the most effective way as possible. One part of communicating risk involves discussing the chance that a person will develop certain types of cancer. For some cancers, empiric estimates of absolute risk are available for those with moderate- and high-risk family histories. When possible, it is important to provide interval risks (over a certain period of time) in addition to lifetime risks. For example, the National Cancer Institute's breast cancer risk assessment tool (Gail model) provides 5-year breast cancer risks in addition to lifetime risks (63,64). Lifetime risks should be adjusted in consideration of the current age of the client. For instance, an 80-year-old woman, whose mother had breast cancer at 40, may have started out with a 20% lifetime risk of cancer but she has lived through a majority of this risk at her current age. Absolute risk estimates should be used whenever possible over relative risks as the latter are hard for clients to put into context. For instance, a threefold increase in risk may sound like a high risk, but could translate into a 1 in 1000 risks of cancer or a 30% risk of cancer, depending on the incidence of the cancer in the population studied.

When a hereditary cancer syndrome is suspected or has been identified, syndrome-specific cancer risks should be provided in the context of the likelihood that the client has familial mutation/predisposition to cancer. Most cancer risk estimates available in the medical literature represent the maximal risk of developing cancer and clients need to understand that there is variation in risk between and within families. In addition, some clients may not recognize that the syndrome in their family places them at risk for more than one type of cancer. For instance, a woman who has an *MSH2* mutation but a personal and family history of colon cancer only may not consider herself at risk for uterine cancer. The clinician will have to help her understand, in the context of variable expressivity and reduced penetrance, why she is at risk for the full spectrum of Lynch syndrome cancers even in the absence of a family history of these.

The second part of communicating risk is discussing the probability that a client has a mutation in a cancer predisposition gene. When a mutation has already been identified in a family, determining this risk is generally straightforward and the likelihood that the client will have the mutation can be presented with relative certainty. In contrast, when testing has not yet been done in a family, the limitations and variation in estimates of risks drawn from risk assessment models or clinical

criteria should be presented. Factors that could improve the validity of the estimate, such as verifying cancer diagnoses, should be discussed.

Before communicating risk information, the clinician should inquire about the client's perception of their own risk and knowledge of general population risks. If a client's perception of her own risk is significantly different than her actual risk, the clinician should anticipate that she may have a difficult time accepting the new risk information. Likewise, a client whose view of general population risks of cancer is very different from actual risks that may have a skewed perspective regarding the significance of her own risks. For instance, a client who is given a 7% risk of colon cancer may feel that this is a very high risk if she does not realize the population risk is 5–6%.

As illustrated above, a portion of the educational component of a cancer genetic counseling session involves educating the client about risk. Other components include any or all of the following: describing the different classifications of cancer in families—sporadic (low or population risk), familial (moderate risk) and hereditary (high risk, Mendelian inheritance) and how family history information is used to distinguish between the different classifications; reviewing the genetics of cancer and the role of somatic versus germline mutations in carcinogenesis; discussing the natural history (associated cancers, risks, and other physical features) of relevant cancer genetic syndromes; reviewing screening recommendations and preventative measures based on the client's risk; discussing the option of genetic testing, when applicable, to further assess cancer risk; and providing informed consent for genetic testing. Important elements of informed consent in genetic testing for cancer predisposition include who is/are the best candidate(s) in the family for testing, the likelihood of a positive result, the significance of a positive versus negative (normal) test result, the possibility of a variant of uncertain significance, how the results of genetic testing may affect clinical management, timing and readiness for genetic testing, current protections against genetic discrimination, psychological risks of testing including survivor's guilt, and the importance of informing other relatives when a mutation is identified (65).

The information shared during a cancer genetic counseling session most commonly triggers decisions about genetic testing and clinical management. Clients may be considering whether to pursue genetic testing or whether to ask another (more informative) relative to consider testing first. In some cases, the client may feel that the decision to test is not theirs alone. For instance unaffected family members may pressure an affected relative to undergo testing to provide genetic information for the rest of the family. In such cases, the genetics professional can help the client weigh the benefits and risks of testing for her and her family and discuss how to communicate her testing decision to relatives.

Sometimes parents are faced with making a decision about testing a child. Several organizations have policies or position statements that support deferring predictive testing for late-onset disorders, such as cancer until adulthood, and/or the child can participate in decision making when there is no medical benefit of testing (66). However, for some hereditary cancer syndromes, such as von Hippel–Lindau syndrome and familial adenomatous polyposis, screening for symptoms is initiated in childhood. In such situations, parents have to weigh the benefits, costs, and risks of screening a child who may or may not have inherited a familial mutation against definitively determining risk in childhood through genetic testing. The genetics professional can be instrumental in helping the parents consider all the consequences of such decisions.

With regard to clinical management decisions, clients may be deciding whether to follow through with screening guidelines or whether to pursue preventative measures such as chemoprevention or prophylactic surgeries. Alternatively, they may be making treatment decisions based on genetic status. For instance, a woman recently diagnosed with breast cancer who has a *BRCA1* mutation may choose bilateral mastectomy over lumpectomy in light of her elevated risk of developing a second breast cancer. When clinical evidence dictates that a specific course of action (such as colonoscopy) is in the best interest of the client, the genetics professional has a responsibility to recommend this course of action. This is very different than the role genetics professionals have in other decisions such as genetic testing or prenatal diagnosis; however, it is an accepted role in cancer genetic counseling.

The primary goal of cancer genetic risk assessment and counseling is to identify individuals at increased risk for the purpose of promoting early detection and prevention. However, a number of psychosocial factors can have an impact on a client's willingness to learn about cancer risk and follow through with clinical management recommendations. Living at increased risk of cancer can trigger a number of emotional responses including anger, anxiety, fear of disfigurement, fear of becoming a burden, fear of dying, grief, guilt, loss of control, negative body image, sadness, sense of isolation and shame (67). These responses can in part be related to personal experiences with cancer, outcomes in relatives with cancer, timing of cancer diagnoses (for instance, during significant life transitions), health belief model, experiences with medical care, familial beliefs about cancer etiology and familial screening/preventative practices. Such factors and experiences may motivate a person to take every precaution necessary to reduce the risk of developing or dying from cancer. On the other end of the spectrum, they may cause a person to deny cancer risks and avoid appropriate medical care. Therefore, identifying, determining the impact of, and discussing a client's psychological reactions to cancer risk are essential elements of effective cancer genetic counseling and risk assessment.

The need for follow-up after an initial cancer genetics consultation varies. Sometimes a cancer genetics consult is limited to one visit, as might be the case for a client at low or moderate risk whose medical management will be coordinated by a primary care physician. Sometimes additional family history information is needed for accurate risk assessment and a second consultation is scheduled to review this new information. When the first consult results in genetic testing, a follow-up consultation for results disclosure is often scheduled, typically in person but in some clinics by telephone. When at the first consult, the client is informed that another relative would be a better candidate for genetic testing, sometimes the client comes back for counseling with that relative or presents a second time independently once the relative has had testing.

When a mutation/syndrome has been identified in a client, follow-up includes a discussion of interval (when available) and lifetime cancer risks, current screening guidelines and available preventative measures, as well as referrals to other health care professionals as needed. The consultation also includes a discussion about risks to other relatives and the importance of notifying them of risk (duty to warn). Some clients also benefit from brainstorming strategies for contacting relatives. The follow-up consultation also provides the clinician an opportunity to assess how well the client is adjusting to the risk information and the likelihood of compliance with medical management. For those in whom noncompliance is a concern, additional follow-up may be warranted.

In summary, cancer genetic risk assessment and counseling is a growing area of genetics services. It is an area of genetics where early recognition of elevated risk can potentially reduce morbidity and mortality and as such significantly change the course of disease in families with generations of early cancer diagnoses and death. As such, the stakes can be high. Therefore, clinicians providing these services need to be well informed about the intricacies of cancer risk assessment, need to stay abreast of evolving phenotypes and changing management guidelines, and need to be willing to identify and address client resistance to optimal medical care.

### 21.3.3 Genetic Testing for Adult-Onset Neurodegenerative Disorders—Huntington Disease

Huntington disease was the first inherited adult-onset disorder for which predictive molecular testing was offered, initially by linkage analysis and then by direct analysis once the causative CAG expansion in the *HD* (*IT15*) gene was identified (68). Guidelines for predictive testing of this autosomal-dominant condition have been available for almost two decades and support a multidisciplinary approach that includes a neurological examination, psychological consultation, and genetic counseling (69). These guidelines have served as a model for predictive and presymptomatic testing protocols for other adult-onset

neurodegenerative diseases such as the spinocerebellar ataxias, early-onset autosomal-dominant Alzheimer disease, and hereditary amyotrophic lateral sclerosis.

Huntington disease is associated with typically adult onset of progressive motor symptoms including chorea, progressive cognitive impairment, and psychiatric disturbances. Symptoms begin on average between the ages of 35–44 years but with a range of 2–80 years. Most die from the disease 15–18 years after the onset of symptoms (70). There is no cure for Huntington disease and predictive testing does not influence clinical management. For this reason, when genetic testing by linked markers became available in the early 1980s, there was considerable debate about whether predictive testing was ethical. However, extensive discussions between clinicians, advocates, and families at risk led to the development of the first predictive testing protocol in 1986 (71).

Benefits of predictive testing for Huntington disease include that it can relieve the uncertainty of not knowing whether one will develop the disease and may be used for life planning, including reproductive decision making. However, uptake of testing has been relatively low, ranging from 3% to 21% (72). As such, it appears that many at risk do not want to know their status. In addition, about 40% of individuals who enter into a testing protocol do not proceed with testing (71). This suggests that pretest counseling plays a critical role in helping those at risk weigh the personal benefits, risks, and limitations of testing. The decision to test should be the client's decision alone. The role of the multidisciplinary team is to make sure that the client is adequately and completely informed; that he has considered the full set of consequences, both positive and negative, of genetic testing in light of his personal circumstances; that he is psychologically ready for the results; and that testing will not lead to adverse outcomes such as suicide.

Smith et al. (73) developed a set of 11 guidelines for genetic counseling and for managing the ethical situations that can arise from Huntington disease predictive testing based on their review of 29 cases. The guidelines tackle a broad array of issues and the counseling conditions necessary to address them appropriately. The issues include confidentiality, (the clinician) refusing or postponing testing, (the client's) freedom to reject disclosure, others preferences not to know genetic status, reproductive choices, and testing children. For instance, the guideline on confidentiality addresses a counselor's ethical obligation to maintain a client's genetic information as private, yet recognizes that an exception may have to be made when there is a "real, pressing, and demonstrable" public safety concern (73). The guideline on "others preferences not to know" addresses the situation where one relative's genetic test will reveal the status of another relative who does not want to know (e.g. child's positive test result revealing parental status) and states that this is not a sufficient reason to deny or delay testing (73).

In terms of counseling conditions, the guidelines developed by Smith et al. speak to the necessity of skilled counseling, the importance of providing appropriate information (anticipatory guidance), and the value of pre- and posttest counseling. These guidelines direct clinicians to learn about a client's experiences with and perspectives on Huntington disease, and the impact that the condition has had the family. They encourage clinicians to use this information to anticipate potential ethical dilemmas or adverse reactions. The guidelines describe the necessary components of pretest counseling and that informed consent goes beyond education regarding natural history and risk to include a discussion of potential psychological sequelae, insurance and/or employment discrimination, and familial repercussions. They also address those circumstances under which the client's request for testing may be refused by the clinician, such as when a client is suicidal or emotionally not able to cope with predictive information (73).

There are a number of questions that the clinicians involved in the predictive testing protocol might ask in assessing a client's experiences, motivations, and readiness for predictive testing. What has it been like having a relative with Huntington disease? Did/does the client have close contact and/or serve as a caregiver for an affected relative or was/is there little contact? Who in the family is considered to be affected, even if she or he has not yet developed symptoms? What does the client think his genetic status is—is he expecting to develop Huntington disease or does he think that he is not at risk? What changes would the client make in his life, plans, or health care if he knew for certain that he would (or would not) develop the Huntington disease? Has the client made any life decisions already based on his anticipated genetic status? How would the information influence reproductive decisions, including possible use of prenatal or preimplantation diagnosis? What are possible economic consequences of learning genetic status, such as loss of health or life insurance? With whom would the client share his results and why? How would having or sharing his genetic status change his relationships with his relatives, spouse, or friends? How would he feel if he was genetically at risk but another close relative was not, or vice versa? Is this the best time to have testing? Why now?

It is also important for the psychologist or other clinicians involved in the predictive testing protocol to specifically ask about the client's mental health history. Does the client have a history of depression or other psychiatric illness? Has he ever required medication or hospitalization for this or had counseling or psychotherapy? Does the client have an ongoing relationship with a therapist, and if so, has he discussed his risk and thoughts about genetic testing with the therapist? Does the client currently feel anxious, depressed, or hopeless? Although prior mental illness is not by itself a contraindication to predictive testing, it may serve as a risk factor for an adverse reaction. Several studies have shown that fewer than 10% of people

undergoing predictive testing for Huntington disease have had a significant adverse event (suicide, suicide attempt or plan, diagnosis of clinical depression, or psychiatric hospitalization) after testing. However, those who did were likely to have had poorer psychological functioning before testing and were more likely to drop out of follow-up studies (74,75). The critical periods for suicide risk are just before receiving a diagnosis and later, when affected individuals experience a loss of independence (76).

For those who proceed with testing, face-to-face results disclosure with the client and at least one support person is most desirable. This provides the predictive testing team an opportunity to assess the client's reactions and to make an appropriate and tailored plan for follow-up. It is important to recognize that carrier status alone (carrier versus noncarrier) does not determine how a client will respond to results. A noncarrier may be relieved that neither he nor his children are at risk. Alternatively, a noncarrier who has lived her life thinking she is a carrier and who has made major life decisions based on this supposition may be unprepared for her new status. A noncarrier may also feel survivor's guilt or be distressed by her newly defined role as family caregiver rather than patient. As such, follow-up for both carriers and noncarriers may be warranted.

In summary, Huntington disease is an incurable, adult-onset neurodegenerative disease, which by virtue of its autosomal-dominant inheritance pattern, can have a significant impact on the families affected. Although identifying risk presymptomatically does not change medical management or the course of the disease at this time, a subset of at-risk individuals find value in learning their status. For those interested, testing should ideally be done in the context of a multidisciplinary approach that includes a neurological examination, psychological evaluation and genetic counseling. Skilled pre- and post-test genetic counseling that helps the client in identifying and taking into consideration his experiences, perceptions, motivations, and readiness for predictive testing is essential. Once counseling has been provided, the client should have the right to make his own decision about predictive testing, without pressure or coercion. For those who have testing, adequate posttest support, particularly at critical periods in the natural history of the disorder, is important in preventing adverse outcomes.

The Huntington disease predictive testing protocol has served as the model for predictive testing in other adult-onset conditions. Some of these conditions are similar to Huntington disease in prognosis and outcomes and some are different in important ways. Clients and clinicians invest (out of necessity) a lot of time in this protocol. Given the limited number of experienced professionals available, this has the potential of limiting access to services. Thus, as more predictive genetic tests become available, it will be important to evaluate for which conditions this protocol is vital and when alternative methods can achieve informed consent and positive counseling outcomes.

## 21.4 GENETIC RISK ASSESSMENT AND CALCULATION IN THE CLINICAL SETTING

As previously mentioned, accurate risk calculations are an important part of the genetics assessment. Genetic counselors are called upon to provide a variety of risk calculations and estimates for known single-gene disorders, multifactorial conditions and teratogens. In order to provide the most accurate and individualized risk, one must be able to collect and interpret client pedigrees, consider limiting factors within a pedigree and be aware of genetic factors that can modify gene expression. Below is a discussion of the risk assessment process and considerations in the genetic counseling practice.

### 21.4.1 Mathematical Methods of Risk Calculation

Risk calculation relies on the application of Mendelian genetic principles of inheritance patterns that may then be further modified or conditioned using mathematical principles such as Bayesian analysis and the laws of addition and multiplication for individualized risk assessment. The Unified Approach to Bayesian analysis is useful when there are numerous variables to consider modifying a risk. This method relies on the “Rule of All Configurations” and “The Rule of Fundamental Probabilities” (77). The appropriate applications of these mathematical principles result in a quantitative risk assessment that can incorporate information such as genetic test results, physical findings, and the number of unaffected individuals in a family to adjust a Mendelian risk derived from known inheritance patterns for individualized risk assessment.

The laws of addition and multiplication are important concepts to understand in order to apply quantitative risk assessment. The law of addition (“or”) states that if two (or more) events are mutually exclusive, and if the probability of event 1 occurring is  $P_1$  and that of event 2 occurring is  $P_2$ , then the probability of either the first event or the second event occurring equals  $P_1 + P_2$ . For example, twins can be either monozygotic (MZ) or dizygotic (DZ) but they cannot be MZ and DZ. Therefore, the probability that they will be either MZ or DZ equals 1. The law of multiplication (“and”) is applied when two or more events are independent. For example, for DZ twins born to parents who are carriers for CF, the probability that both the first and second twins will have CF is  $1/4 \times 1/4 = 1/16$ .

Example 1: Healthy parents have had a child with a severe autosomal-recessive disorder (Figure 21-1). They are counseled about autosomal-recessive inheritance and are informed that they have a 1/4 chance to have a child that is affected, a 1/2 chance to have a child that is an unaffected carrier and a 1/4 chance to have a child that is an unaffected noncarrier for the condition. Their next pregnancy is determined to be a twin pregnancy. The parents now wish to know the probability that at

FIGURE 21-1 Pedigree for example 1.

least one twin will be affected by the autosomal-recessive disorder. Zygosity has not yet been established.

To answer this question, the risks are first calculated for the two mutually exclusive possibilities that the twins are either (1) MZ ( $P = 1/3$ ) or (2) DZ ( $P = 2/3$ ).

1. *Monozygotic*. In this situation, the probability that both twins will be affected equals 1/4, that only one will be affected equals 0, and that both will be unaffected equals 3/4.
2. *Dizygotic*. If the twins are DZ, then the genotype of one twin does not influence the genotype of the other twin (i.e. these events are independent). Therefore, the probability that both twins will be affected equals 1/16 (i.e.  $1/4 \times 1/4$ ), the probability that only one will be affected equals 3/8 [i.e.  $(1/4 \times 3/4) (3/4 \times 1/4)$ ], and the probability that both will be unaffected equals 9/16 (i.e.  $3/4 \times 3/4$ ).

Using this combination of mutually exclusive and independent events, the parents' question can now be answered. The overall probability that

- (a) both twins will be affected equals  $1/3 \times 1/4$  (MZ) plus  $2/3 \times 1/16$  (DZ), giving a total probability of 1/8;
- (b) only one twin will be affected equals  $1/3 \times 0$  (MZ) plus  $2/3 \times 3/8$  (DZ), giving a total probability of 1/4;
- (c) both twins will be unaffected equals  $1/3 \times 3/4$  (MZ) plus  $2/3 \times 9/16$  (DZ), giving a total probability of 5/8.

With this information, the parents can be reliably informed that there is a probability of  $1/8 + 1/4 = 3/8$  that at least one of their unborn babies will be affected. Another way to approach answering the same question is to subtract the chance that neither baby will be affected from 1.

### 21.4.2 Bayes Theorem

The application of Bayes theorem enables one to calculate a conditional probability or risk considering one or more conditions or events (such as carrier or

noncarriers, affected or unaffected) and then weighing or “conditioning” these by incorporating relevant information. The incorporation of all possible conditions will enable one to derive a risk for a specific individual in a specific family and avoid generalized estimates that may be gross over- or underestimates of risk. It is important to consult with colleagues when calculating complex cases with multiple factors.

The initial probability of each event is known as its prior probability and is based on “anterior” information such as the phenotypic findings and/or family history. The observations that modify these prior probabilities allow conditional probabilities to be derived from “posterior” information such as the results of a carrier tests. The resulting probability for each possibility or event is known as its joint probability (prior probability  $\times$  joint probability). The Unified Approach’s Rule of All Configurations requires one to determine all possible genetic configurations in family and calculate the joint probabilities for each configuration and then use this information to determine the posterior probabilities (77). The overall final probability of each event, which is known as its posterior or relative probability, is obtained by dividing its joint probability by the sum of all the possible joint probabilities. A table (Table 21-8) can be utilized to apply Bayes theorem to clinical situations and the table should be drawn up that include all relevant possibilities and that all informative observations should be used once and only once. The following example utilizes this theorem in a clinical setting.

Example 2: The consultant, II<sub>1</sub> in Figure 21-2, wishes to know the probability that her male fetus will have X-linked hemophilia. She has one previously unaffected son. She had a brother and two maternal uncles with a clinical diagnosis of the condition but no molecular testing is available. In order to answer this question for her, one must calculate her chance to be a carrier considering the family history information and then her chance to pass on the gene for hemophilia if she is a carrier.

On the basis of the family history information, her mother is an obligate carrier for the condition. This anterior information allows us to assign II<sub>1</sub>, a prior probability of being a carrier as 1 in 2. Similarly her prior probability of not being a carrier also equals 1 in 2. These are mutually exclusive events, and the sum of their probabilities equals 1.

This consultant already has one unaffected son. This information decreases her chance to be a carrier. The conditional probability that a carrier would have an unaffected son is 1/2. The conditional probability that II<sub>1</sub> would have one unaffected son if she is not a carrier equals 1, that is,  $1 \times 1 = 1$ .

All this information is now incorporated in a Bayesian table (Table 21-9). The posterior probability that II<sub>1</sub> is a carrier equals 1/3 and the chance she is not a carrier equals 2/3. Considering that this is an X-linked condition, there is a 50% chance she would pass on the genetic

**TABLE 21-8 Basic Bayesian Calculation Table for One Condition**

	Outcome A (Example: Carrier or Affected)	Outcome B (Example: Noncarrier or Unaffected)
Prior	a	b
Conditional	c	d
Joint	ac	bd
Posterior	$\frac{ac}{ac + bd}$	$\frac{bd}{ac + bd}$

**FIGURE 21-2** Pedigree for example 2.

**TABLE 21-9 Example 2 Bayesian Table**

	II <sub>1</sub> Carrier	II <sub>1</sub> Noncarrier
Prior	1/2	1/2
Conditional (1 prior unaffected male)	1/2	1
Joint	$1/2 \times 1/2 = 1/4$	$1 \times 1/2 = 1/2$
Posterior	$\frac{1/4}{(1/2 + 1/4)} = 1/3$	$\frac{1/2}{(1/2 + 1/4)} = 2/3$

mutation to her male fetus if she was a carrier; therefore, the chance for an affected male fetus equals 1/3 (II<sub>1</sub> carrier risk)  $\times$  1/2 (chance to pass on the affected X) = 1/6 and the chance of an unaffected male fetus is 5/6.

### 21.4.3 Application of the Hardy–Weinberg Law in Risk Assessment

The Hardy–Weinberg law is a fundamental principle of population genetics that can be applied to determine the carrier frequency in a population of an

autosomal-recessive condition. The Hardy–Weinberg law states that if the frequency of the normal (wild-type) gene equals  $p$ , and the frequency of the abnormal (mutant) gene equals  $q$  so that  $p + q = 1$ , then the incidence of noncarriers, carriers, and affected will be  $p^2$ ,  $2pq$ , and  $q^2$ , respectively. This conclusion applies if the population is in Hardy–Weinberg equilibrium and involves several assumptions:

1. A large, randomly mating stable population.
2. Either a constant mutation rate, which balances out those genes lost because of death of affected homozygotes, or no new mutations and no selection against affected homozygotes.
3. No selection for or against carriers.

These assumptions are not always valid, and special care should be taken not to calculate carrier frequencies when the disease incidence has been derived from a small consanguineous community. For practical counseling purposes, these limitations can usually be ignored.

If the Hardy–Weinberg law applies, then the incidence ( $I$ ) of carriers in the general population, which will equal the probability that a healthy member of that population is a carrier, will approximate to twice the square root of the disease incidence ( $q^2$ ), that is

$$I = 2 \times p \times q (= 2q \text{ as } p \text{ is very close to } 1)$$

Therefore, for conditions such as cystic fibrosis and phenylketonuria, which have incidences of approximately 1 in 2500 and 1 in 10,000, respectively, the respective carrier incidences will be

$$2 \times \sqrt{(1/2500)} = 1/25$$

$$2 \times \sqrt{(1/10,000)} = 1/50$$

The ability to apply the Hardy–Weinberg law will enable one to calculate the carrier frequency of a recessive disease with a known disease incidence. This is helpful when calculating a risk for an affected child when one parent has a family history of a specific autosomal-recessive condition and the partner's carrier risk is equal to the general population.

#### 21.4.4 Calculating Risk for At-Risk Family Members and Autosomal-Recessive Conditions

Determining the recurrence risk for a couple that has had a child with a recessive condition is generally straightforward based on Mendelian inheritance. The assumption is that both parents are carriers and there is a 1/4 chance with each additional pregnancy to have another affected child. It is important to remind clients that each pregnancy is a new event and that one affected child does not translate to three subsequent unaffected children. Informative molecular testing on the affected

individual can allow for carrier testing in family members. There are genetic mechanisms that may make this untrue such as a new mutation of a recessive allele as seen in spinal muscular atrophy or uniparental disomy of the recessive allele as reported in cystic fibrosis, but these are very rare. One must also consider possible false paternity if the reported father does not share a known allele with the affected child.

The probability that the healthy full sibling of an affected individual is a carrier equals 2/3 rather than 2/4, as the fact that the sibling is unaffected means that the denominator is 3 and not 4. It is important to document full siblings and half siblings as their risk to be a carrier will be different. The unaffected half sibling to an individual with an autosomal-recessive condition will have a 1 in 2 chance to be a carrier for the condition. The risks to extended family members of an affected individual are smaller than siblings' risk but usually increased over the general population and can be calculated by tracing the relationship through the pedigree.

Example 3: For example, the female first cousin of an individual with cystic fibrosis (CF) will have a 1 in 4 chance to be a CF carrier as compared to the approximate general population risk of 1 in 25 in the non-Hispanic Caucasian population (Figure 21-3). This information can then be used to determine her chance to have a child with CF.

In this case, if one assumes that both members of the couple are non-Hispanic Caucasian and there is no family history of CF on the father's side of the family, the chance of an affected pregnancy would be calculated by multiplying the mother's carrier risk (1 in 4) by the father's general population carrier risk (1 in 25) by 1 in 4 (chance of two carrier parents to have a child with an autosomal-recessive condition). Their chance to have a child with CF is 1 in 400, which is significantly increased over the general population chance for a non-Hispanic Caucasian couple with no family history of 1 in 2500. If there is consanguinity in the family, the risk for an autosomal-recessive disease may be significantly increased depending on the degree of the relationship between the parents.

FIGURE 21-3 Pedigree for example 3.

### 21.4.5 Modifying Factors in Mendelian Conditions and Accurate Risk Assessment

Numerous genetic factors may influence the expression of a condition within an individual or family and these factors should also be considered when determining the risk of a condition for an individual. These factors include reduced penetrance, variable age of onset, somatic or germline mosaicism, and new mutations. These concepts are reviewed here related to risk assessment in the clinical setting and detailed discussions of these principles in other places within this text.

### 21.4.6 Reduced Penetrance

Reduced penetrance is observed in conditions in which only a portion of individuals with a specific genotype express the phenotype associated with the mutation. Individuals who fail to express the condition but carry the mutation can pass on the condition to their offspring, who may express the condition. Penetrance is an all-or-none concept and it remains unclear the factors that influence penetrance. It is presumed that other genes, allelic or nonallelic, somehow influence expression of the relevant allele. Alternatively, expression of an allele may require a second and somatic mutational event, which must occur within a specific organ and time frame. This concept presents a challenging counseling dilemma and a great deal of uncertainty for the client. It is important to explain the concept clearly when discussing the implications of a condition that is known to have reduced penetrance. Retinoblastoma and split-hand deformity are two autosomal-dominant conditions with known reduced penetrance. In these families, it may appear to the family that the condition is “skipping a generation” when in fact the genetic mutation is present, but not expressed. Knowledge of the expression of a condition can be applied to Bayesian analysis to calculate the risk for an individual to have an affected offspring or to be a carrier him or herself.

**Example 4:** Consider the pedigree below (Figure 21-4). This is a known autosomal-dominant trait in which 70% of individuals with the mutation will express the condition and 30% will be nonexpressing carriers with a 50% chance to pass the allele on to each child. In this case, the penetrance ( $P$ ) is calculated as 0.7. The consultant would like to know her risk to be an unaffected carrier.

This result estimates her chance to be a nonexpressing carrier of the mutation for the disease in question is approximately 3/13 or 23% (Table 21-10).

Furthermore, her chance to have an affected child would be:

$3/13$  (her chance to be a carrier)  $\times 1/2$  (chance to pass on dominant allele)  $\times 0.7$  (penetrance) = 0.08 or 8%.

**FIGURE 21-4** Pedigree for example 4.

**TABLE 21-10** Bayesian Analysis for Example 4

	Carrier	Noncarrier
Prior	1/2	1/2
Conditional	3/10	1
Joint	$1/2 \times 3/10 = 3/20$	1/2
Posterior	$\frac{3/20}{3/20 + 10/20}$	$\frac{10/20}{3/20 + 10/20}$

### 21.4.7 Variable Age of Onset and Late-Onset Disorders

While a germline mutation for a genetic condition is present from the time of conception, when the mutation expresses itself can be variable based on the condition. In some conditions, the expression of that mutation may be so significant that it is lethal in utero or a prenatal ultrasound will reveal anomalies suggestive of the condition. In others, it may not express until childhood or well into adulthood. For the parents of children at risk for conditions that express in later childhood such as some forms of spinal muscular atrophy or Duchenne Muscular Dystrophy (DMD), the watch and wait period can be agonizing. For conditions that do not express until adulthood, there are unique counseling considerations because the at-risk individual may have already had children of their own and unknowingly passed on the condition to their children.

It is important to be knowledgeable of the typical age of onset for a particular condition in order to accurately evaluate and interpret a medical exam and/or family history. For example, a normal neurological exam in an 18-year-old male who has two siblings ages 16 and 24 and a 55-year-old parent with Huntington's disease is of little clinical value to reassure him that he did not inherit the condition because he is younger than the mean age on onset (35–44 years). However, if the consultant is 78 and his siblings are 76 and 84 and none of them have developed neurological symptoms of the condition, it is much less likely that anyone of them inherited the condition from their parent.

Increasingly, genetic testing is available for many conditions with variable or late onset; however, an

unaffected at-risk individual may or may not choose to be tested for the condition due to a multitude of concerns about the implications for their own health, their children and other family members and concerns related to genetic discrimination. In this situation, the clinical information and family history information can be used applying Bayesian analysis to modify an individual's genetic risk. Accurate risk assessment is also helpful in deciding if a test is worth the financial costs based on a client's risk to carry the condition.

**Example 5:** Two sisters request counseling for an autosomal adult-onset disorder that is affecting their mother (Figure 21-5). Both women are in their 40s. The penetrance for the disorder at their age is 44% and the sporadic risk is 4%.

Using Bayesian analysis, their chance of carrying the disease-causing allele has been reduced from 50% to 37% (Table 21-11).

**FIGURE 21-5** Pedigree for example 5.

### 21.4.8 Germline Mosaicism and New Mutations

When providing recurrence risk counseling for a couple that has had a child with an autosomal-dominant condition and the family history is negative for the condition, one must consider the proband as having a new mutation in the family or germline mosaicism in one of the parents. The potential recurrence risk in each case will likely be significantly less than the expected 50% if one parent were affected, but should be established for the client. A new mutation expresses when a proband has a mutant allele on one locus that is not inherited from either parent. For conditions with variable expression such as neurofibromatosis, a careful examination of the parents for any previously unrecognized medical symptoms of the condition should be done to confirm that both of the parents is truly unaffected.

Germline mosaicism is a result of postzygotic mutation in an individual's gametes that results in all or a portion of their gametes harboring the mutation for a specific condition that is not otherwise phenotypically expresses in the individual. Germline mosaicism has been reported in numerous conditions (OI, NF1, retinoblastoma) (78) and clients should be counseled about potential for recurrence in a family that has been previously unaffected.

### 21.4.9 Direct Mutation Analysis and Multiple Alleles

While genetic testing is available for a growing number of conditions, in some instances, the testing does not identify all mutated alleles in individuals with a specific genetic condition or as a part of general population screening for a common condition. CF is one

TABLE 21-11	Bayesian Analysis for Example 5	
	Woman is Aa	Woman is aa
Prior	0.50	0.50
Conditional (unaffected)	$1 - 0.44 = 0.56$	$1 - 0.44 = 0.96$
Joint	$0.50 \times 0.56 = 0.28$	$0.50 \times 0.96 = 0.48$
Posterior	$0.28 = 0.37$	$0.48 = 0.63$
	$0.28 + 0.48$	$0.28 + 0.48$

example of a relatively common genetic condition with over 1000 disease-causing alleles but only a fraction of those are part of the population screening program based on the frequency of specific mutations in certain ethnic groups. ACMG recommends testing for only 23 of these mutations for general population screening (79). Routine carrier screening of the non-Hispanic Caucasian population will identify approximately 90% of gene carriers and it will identify 97% of carriers in the Ashkenazi Jewish population. Therefore, in this condition, a person who receives a negative carrier test for CF will not have a risk equal to "0" but they will have a significantly decreased risk over their prior risk of the general population. This is an important counseling point when explaining to clients that they can have a negative test but still have a relatively small, but real risk to have an affected child.

**Example 6:** The review of a client's family history reveals that she had a first cousin with CF. Molecular testing was not completed on the affected individual. Both members of the couple are non-Hispanic Caucasians and there is no known history of consanguinity. Both members of the couple have had negative carrier screening. Their risk would be reduced independently based on their prior risk to be a carrier. The mother's risk is shown in Table 21-12 and the father's risk is shown in Table 21-13.

This couple's revised risk to have a child with CF is  $3.2\% \times 0.4\% \times 25\% = 0.0032\%$  (1/33604).

**TABLE 21-12** Example 6 Mother's Bayesian Analysis

Mother's Revised Carrier Risk	Carrier	Noncarrier
Prior	$\frac{1}{4}$	$\frac{3}{4}$
Condition negative carrier test	$\frac{1}{10}$	1
Joint	$\frac{1}{40}$	$\frac{3}{4}$ (30/40)
Posterior	$\frac{1/40}{1/40 + 30/40} = \frac{1}{31}$ (3.2%)	$\frac{3/4}{1/40 + 30/40}$

**TABLE 21-13** Example 6 Father's Bayesian Analysis

Father's Revised Carrier Risk	Carrier	Noncarrier
Prior	$\frac{1}{28}$	$\frac{27}{28}$
Condition negative carrier test	$\frac{1}{10}$	1
Joint	$\frac{1}{280}$	$\frac{27}{28}$
Posterior	$\frac{1/280}{1/280 + 270/280} = \frac{1}{271}$ (0.4%)	$\frac{270/280}{1/280 + 270/280}$

### 21.4.10 Risk Assessment in X-Linked Conditions

When reviewing family histories for X-linked conditions, it is important to appreciate the difference in risk assessment for an isolated case of the condition in a family or if there are multiple affected family members. For a woman who has a brother and a son with DMD, it is clear based on Mendelian inheritance that she is an obligate carrier for the condition and her risk to have another affected son is 50% and each of her daughters will have a 50% chance to be a DMD carrier.

However, determining the risk associated with X-linked recessive lethal conditions becomes more challenging when it is the first incidence of the condition in the family (Figure 21-6). Because severe X-linked conditions have a rate of de novo or new mutations, the challenge in these cases lies in determining in whom the pathogenic mutation began in a family. They may be the result of a new mutation in the affected male, a new mutation in the mother passed on to the affected male, or a mutation in the maternal grandmother passed on to the mother of the affected male. Specifically to calculate the prior probability of a carrier state in female relatives of an isolated case of an X-linked lethal disorder, one must consider (1) whether the mother of an affected son inherited the mutation from her mother; (2) whether the mother has a newly mutated allele on the X chromosome she inherited from her mother or (3) whether the mother has a newly mutated allele on the X chromosome she inherited from her father. Historically, the assumption

**FIGURE 21-6** Pedigree for X-linked recessive lethal condition.**TABLE 21-14** X-Linked Lethal New Mutation

	Mother Carrier	Mother Noncarrier
Prior	$4\mu$	$1-4\mu$ (approximately 1)
Conditional (affected son)	$\frac{1}{2}$	$\mu$ (new mutation in the X her son inherited from her)
Joint	$2\mu$	$\mu$
Posterior	$\frac{2\mu}{2\mu + \mu} = \frac{2}{3}$	$\frac{\mu}{2\mu + \mu} = \frac{1}{3}$

has been that there are equal mutation rates per locus per meiosis in males ( $\nu$ ) and females ( $\mu$ ). The mother in the first generation is not a carrier, and affected males are unable to reproduce (genetic fitness = 0). In the second generation, the probability that a female will be a carrier equals  $2\mu$ . In the third generation, this value raises to  $3\mu$ , that is, half of the mother's probability of  $2\mu$  plus  $2\mu$ . By generation  $n$ , this probability of heterozygosity will have reached  $4\mu$ . This then is the value for the prior probability that any female who does not have a positive family history will be a carrier of a sex-linked recessive disorder with zero fitness in affected males when mutation rates are equal in the sexes.

The mathematical result in this situation results in 1/3 of cases the male with the condition is the result of a new mutation and in 2/3 of cases the mother is the carrier (Table 21-14).

Using Bayesian analysis (Table 21-15), the risk that the maternal grandmother of an isolated case is a carrier is 1/3 (Figure 21-7). Knowledge of this information makes it easy to calculate the carrier risk for extended female relatives.

Interestingly, there are now studies that suggest that the new mutation rates for certain conditions such as X-linked myotubular myopathy and DMD differ in male and female germ lines (80), which would have an impact on calculating the carrier probabilities in X-linked disorders.

**TABLE 21-15** Bayesian Analysis for X-Linked Lethal Condition

	Maternal Grandmother Carrier	Maternal Grandmother Noncarrier
Prior	$4\mu$	$1-4\mu$ (approximately 1)
Conditional (affected grandson)	$1/4$	$2\mu^a$
Joint	$4\mu \times 1/4 = \mu$	$1 \times 2\mu$
Posterior	$\mu = 1/3$	$2\mu = 2/3$
	$2\mu + \mu$	$2\mu + \mu$

<sup>a</sup> $\mu$  (new mutation in affected grandson) +  $1/2 \times 2\mu$  (chance that grandson inherited a mutation from his mother that was a new mutation in her).

**FIGURE 21-7** Pedigree for isolated case of X-linked lethal condition.

### 21.4.11 Incorporating Laboratory Results and Clinical Findings

In some cases, the estimate of an individual risk may be modified based on certain laboratory and molecular test results or clinical findings that can modify the risk for a genetic condition. The incorporation of these factors by

Bayesian analysis will provide a client more accurate and individualized risk estimate that then can be used to help them in understanding the true chances of a condition occurring and their next course of action. The individual providing genetic counseling should be well versed in the sensitivity and specificity of the result and/or clinical finding and the scientific literature available to support the modification of an individual's risk.

**Example 7:** A non-Hispanic Caucasian woman is seen for a prenatal ultrasound and echogenic bowel is discovered. Echogenic bowel can be a clinical ultrasound finding in a fetus with CF. She is a known CF carrier. Her partner has a full sibling with CF but has not pursued carrier testing because of insurance issues. His prior risk of being a carrier is  $2/3$ . The counselor must make several assumptions based on the current literature discussing echogenic bowel and CF in order to modify the chance, the fetus is affected. The example below assumes that the probability that a fetus has echogenic bowel if it has CF is 0.11 and the probability that a fetus has an echogenic bowel is a carrier for CF is 0.00098 and the probability that the fetus has an echogenic bowel and is not affected and not a carrier is 0.00035 (81).

The probability of an affected fetus in this case is 97% (Table 21-16). On the basis of this significant increased risk, prenatal diagnosis could be considered. The client should be counseled about the limitations of prenatal diagnosis if only her mutated allele is identified. Full sequencing of the *CFTR* gene could be considered if the father of the baby remained unavailable for testing.

### 21.4.12 Family History Considerations in Risk Assessment

Accurate family history collection is invaluable for risk assessment purposes. The recurrence risk for Mendelian single-gene disorders should be determined based on the known mode of inheritance for the condition. This assumes that the diagnosis in the proband is correct and the family member is knowledgeable about the family history. Information related to a diagnosis is easily confirmed if one is providing risk estimates for the proband or close family members, however, it can become more difficult for extended family members if they have incorrect or incomplete information about the condition in the family. Collection and review of medical records on

**TABLE 21-16** Bayesian Analysis to Incorporate a Clinical Finding

Father	Carrier	Noncarrier
Prior	$2/3$	$1/3$
Fetus (given carrier mother)	Affected 0.25	Carrier 0.5
Cond.-EB present	0.11	0.00089
Joint	0.0183	0.0002963
Posterior	0.97	0.016

NC = Noncarrier; EB = Echogenic bowel.

the proband, when possible, will enable one to more confidently provide assessment.

Several factors may make the interpretation of a client's pedigree challenging and should be considered when collecting and interpreting a family history for risk assessment. A small family size may not provide the counselor with a lot of information to determine inheritance patterns and to differentiate between a sporadic or familial condition. Individuals who are adopted often have little or no information about their biological family to base risk assessment on. Some clients may withhold essential information such as false paternity or illegal drug use for fear of being stigmatized. False paternity can lead to the collection of information that is irrelevant to an individual resulting in an over- or underestimation of their risk for a genetic condition. And certain pregnancy exposures such as illegal drugs, medications or alcohol may not be disclosed by a client but can have associated phenotypes that might mimic a single-gene disorder as well as carry a specific teratogenic risk.

### 21.4.13 Consanguinity

Consanguinity and inbreeding may significantly impact the occurrence and recurrence of autosomal-recessive conditions and congenital anomalies. In some instances, couples may request genetic counseling because of consanguinity or it may be revealed after the birth of a child with a genetic condition or birth defect. It is prudent to ask about consanguinity in all genetic counseling sessions, either in relation to the client couple or in some past relationship in the family.

Determining the degree of relationship between the proband and the affected individual is also important. For example, many individuals are unaware of the difference between a first cousin, second cousin and first cousin once removed. While this may seem trivial to a client, it has significant implications to the amount of genetic information that they share in common with a proband and the risk for a recessive condition in a consanguineous mating (Table 21-17). Accurate degrees of

relationship are required to provide counseling for carrier status of autosomal-recessive and X-linked recessive conditions. This is also important information when counseling consanguineous couples. The degree of relationship is used to calculate the coefficient of inbreeding (F) for consanguineous couples. The coefficient of inbreeding is defined as the probability that homozygote for a condition received both alleles at a locus from a common ancestor (identical by descent).

### 21.4.14 Empiric Risk for Chromosome Aneuploidies and Multifactorial Conditions

Empiric data is used to assess the risk for presumably multifactorial conditions, when available. These data are derived from observations of many apparently similar cases that may actually have varying etiologies, and although they might be the best risk figures that exist, they may not be accurate for a given family. Given the roles of modifying genes and environmental factors, this may also be true of the data we have on the likelihood of specific complications occurring in variably expressed Mendelian disorders. In these types of situations, providing specific risk figures may imply a level of precision that is misleading and clients should be informed of the limited utility of this generalized information to a specific individual.

The risks for occurrence and recurrence of chromosome aneuploidies are also based on empirical data collected on pregnancy outcomes from large populations of women. These data are collected based on the pregnancy outcome at the woman's age at delivery, not her age at the conception of the child. These studies have revealed that the primary risk factor for having a child with a chromosome aneuploidy is maternal age (82). Providing this information to clients allows each individual to know their specific age-related risk and compare that risk with other factors such as risks for aneuploidies derived from serum screen results and the risk of invasive prenatal diagnostic testing.

### 21.4.15 Risk for Disease Expression

As a part of comprehensive risk assessment during genetic counseling, it is important to discuss the risk of the potential manifestations of a condition with known genetic factors. This may include the risk for specific cancers over a lifetime in individuals with a known *BRCA* or Lynch syndrome associated mutation or the chance of developing a deep vein thrombosis for an individual that is homozygous for a Factor V Leiden mutation. For example, after an absolute genetic risk is determined, such as a 50% risk for a *BRCA1* mutation in the daughter of an individual with a known *BRCA* mutation, risk figures are also provided for the risk of breast and ovarian cancer as compared to the general population. These figures are provided in an attempt to demonstrate an increased risk, and to assist a client in making medical decisions. In most

TABLE 21-17

Degree of Relationship	Proportion of Genes in Common	Coefficient of Inbreeding (F)
First (parent–child; brother–sister)	1/2	1/4
Second (brother–half sister; uncle–niece; aunt–nephew; double first cousins)	1/4	1/8
Third (half-uncle–niece; first cousins)	1/8	1/16
Forth (First cousins once removed)	1/16	1/32
Fifth (Second cousins)	1/32	1/64

cases, these risk numbers are based on cohort data from other individuals with a *BRCA 1* or 2 mutations. It can be difficult to quantify for clients other factors such as ethnic background, lifestyle choice and modifying genetic variants that determine why one person develops cancer and another family member with the same genetic change will live to an advanced age and never develop cancer.

### 21.4.16 Closing Thoughts

Summarizing the field of genetic counseling, the genetic counseling process and clinical risk assessment in one coherent chapter is a challenge because of the breadth of the field and the rapid advances in medical genetics. This chapter aims to provide readers with an awareness of the fundamental applications of the field and encourage further readings on topics of interest. The process of genetic counseling is unique in many ways from other areas of medicine because of the sometimes nondirective nature, holistic medical evaluation of the client and their family history, and the integration of psychosocial assessment and support. Individuals who provide genetic counseling are able to analyze large volumes of analytical information yet communicate it on the most basic level if needed to assist a client in understanding and utilize the information. This skill set is no doubt shared by many in health care and will continue to be important as genomic medicine becomes integrated into all areas of medicine.

### ACKNOWLEDGMENTS

We would like to acknowledge the previous author of the Genetic Counseling chapter, Anne P Walker, and Ian D Young, the previous author of the previous Risk Estimation in Genetic Counseling chapter. Their thoughtful work was of great value in constructing this chapter. We also would like to acknowledge our colleagues, students and clients who have all inspired and supported us in our professional pursuits.

## Biographies

**R Lynn Holt, MS, CGC** is a certified genetic counselor, assistant professor, and the founder of the University of Alabama at Birmingham Genetic Counseling Program. She instructs genetic counseling, doctoral, and medical students about genetic counseling principles, medical genetics, prenatal genetics and nontraditional roles in genetic counseling. She provides clinical genetic counseling for clients with a familial predisposition to cancer. She is an active member of the National Society of Genetic Counselors and past board member.

**Angela M Trepanier, MS, CGC** is a certified genetic counselor, assistant professor of molecular medicine and genetics, and director of the Wayne State University Genetic Counseling Program in Detroit, MI. She provides instruction in medical genetics to a wide variety of student, professional and lay audiences. Her research interests include medical genetics education and genetic counseling service delivery models. Angela is a past president of the National Society of Genetic Counselors and a member of the National Coalition of Health Professional Education in Genetics board of directors.

### 22.1 INTRODUCTION

Cytogenetics traditionally refers to the study of chromosomes by microscopy following the application of banding techniques, permitting identification of abnormalities of chromosome number, loss or gain of chromosomal material or positional changes. Advances over the past 30 years have resulted in an increased reliance on molecular techniques, such that the current field is a hybrid of microscopic and molecular based technologies. Because chromosomes carry the genetic material, an understanding of their behavior, structure, and function is essential to an understanding of genetics. Visible or submicroscopic changes in the number and structure of chromosomes have been associated with a broad spectrum of disease, and so the analysis of chromosomes has been an important tool in medical genetics for decades. Key technical advances in chromosome analysis include fluorescence in situ hybridization (FISH), first introduced in the mid-1980s, and then array-based genomic analysis or chromosome microarray analysis (CMA), introduced in the 1990s and brought into clinical practice beginning around 2003 (1–3). This chapter describes the most useful techniques of those now available for chromosome analysis. In recent years, array-based techniques have become the first line of investigation for analysis of chromosome abnormalities, with cytogenetic and FISH tools utilized to help interpret the results of imbalances diagnosed by array. Array-based techniques generally only identify imbalances resulting in deletions or duplications; there are cases of balanced translocations, inversions or ring chromosomes that can only be identified currently by standard chromosome analysis (4).

### 22.2 MILESTONES IN HUMAN CYTOGENETICS

Human chromosomes were probably first observed by Arnold in 1879 by dividing tumor cells. Hanseman in 1891 and Flemming in 1898 attempted to count the number of chromosomes in serial sections of dividing cells and obtained crude estimates of about 24. Quite different results were reported by de Winiwarter in 1912. He seems to be the first to study sections of gonadal tissue, and he found counts of 47 in testes and 48 in ovary. He interpreted these results by indicating that, like some invertebrates, males had a single X chromosome and females had two. In 1921, Painter demonstrated in testis sections the presence of an additional small Y chromosome that was overlooked by de Winiwarter. Although he assumed that 48 was the correct chromosome number in both sexes, it is interesting to note that in his 1921 paper he states that he could count only 46 chromosomes in the clearest mitotic figures. In a paper published in 1923, Painter predicted the existence of individuals with unusual combinations of sex chromosomes, in particular intersexes with an XXY sex chromosome complement. No one seems to have tested this idea until 1942, when Severinghaus described an XY sex chromosome constitution in an XY female. Largely as a result of the unfavorable material available for studying human chromosomes, there were few reports on this subject until the early 1950s. An important exception was a paper by Koller (1937) in which the X–Y pairing segment in human meiosis is described for the first time and the possibility of partial sex linkage raised. The possibility that pathologic disorders might be due to abnormalities of

chromosome number and structure seems to have been suggested first by Theodor Boveri. He described his theory on the origin of cancer from chromosomal aberrations in a classic monograph published in 1914. Then, 46 years later, the first specific chromosome abnormality associated with malignancy was described, namely, the Philadelphia chromosome in chronic myeloid leukemia (5). Subsequent developments in cancer cytogenetics have fully confirmed the role of chromosome aberrations in the pathogenesis of cancer and established cytogenetic analysis as an essential component in classification and prognosis. With regard to constitutional chromosome abnormalities, Waardenburg in 1932 was one of the first to suggest that Down syndrome might be due to a numeric chromosome aberration resulting from non-disjunction. This may have prompted Mittwoch (1952) to study testis material from a case of Down syndrome. She counted an average of 24 bivalents in diakinesis and about 48 in spermatogonial mitoses and concluded that the chromosome number was normal. Had hypotonic pretreatment and control material from a normal individual been available, she might have appreciated that the number at diakinesis in Down syndrome was abnormal, with 23 bivalents plus one univalent.

Human cytogenetics became a practical proposition with the discovery by Tjio and Levan (1956) that the correct chromosome number was 46 and not 48 (6). Both of them were experienced cytologists who exploited the availability in their laboratory of fetal tissue culture from abortus material. Levan had earlier introduced into plant cytogenetics the use of colchicine to arrest and accumulate mitoses at metaphase, and he knew about the effect of hypotonic solutions to separate individual chromosomes from one another by pretreatment before fixation. The hypotonic technique had been discovered independently by three scientists, Hsu (1952) in the United States, Makino and Nishimura (1952) in Japan, and Hughes (1952) in England. Apparently, both Hsu and Makino made the discovery fortuitously, after mistakenly adding hypotonic instead of isotonic salt solution during the washing stage before fixation. After fixation, the technique current at that time was to squash the dividing cells between the slide and coverslip so that the chromosomes could be spread in one optical plane. A variety of nuclear stains including aceto-orcein, Giemsa, and Feulgen were used to stain the chromosome preparations. All these methods, especially tissue culture, contributed to the rapid developments in human cytogenetics in the following years.

The chromosome number of 46 was soon confirmed in testis material by Ford and Hamerton (1956). Two years later, Ford et al. (1958) introduced a method for chromosome analysis using bone marrow samples that was suitable for clinical studies in that it exploited the presence of actively dividing cells in that material. At about the same time, Lejeune et al. were reinvestigating the chromosomes in Down syndrome from fibroblast cultures (7).

Their discovery of trisomy for one of the smallest autosomes was announced in 1958, although the description in nine patients was not published until early in 1959. Simultaneously, interest in the chromosomes of the Turner and Klinefelter syndromes was prompted by the paradoxical nuclear sex chromatin (Barr body) findings in 1954 suggesting that amenorrheic women with Turner syndrome might be genetic males, and that infertile men with Klinefelter syndrome might be genetic females. The latter seemed to be confirmed by Ford et al. (1958), who found one Klinefelter patient to have an apparently normal female chromosome constitution on bone marrow preparations (8). However, Ford reported in 1959 that Turner syndrome was usually associated with a 45, X chromosome complement and Jacobs and Strong found that Klinefelter syndrome had a 47, XXY complement (9). The important conclusion from these studies was that human sex differentiation was determined by the Y chromosome and not by the number of X chromosomes.

It came as a surprise to clinicians that such gross numeric chromosome abnormalities could be associated with viability. There followed intense activity worldwide to determine whether other dysmorphic conditions were due to chromosomal abnormalities visible under the microscope. Trisomies 13 and 18 were quickly identified, followed by several instances of sex chromosomal mosaicism, translocation Down syndrome, and the deletion of the short arm of chromosome 5, which causes the cri du chat syndrome (10).

The search for new examples of conditions that are due to chromosome aberrations was accompanied by strenuous attempts to simplify techniques and improve the identification of individual chromosomes so that smaller structural changes could be detected. The most important of these early technical developments was the introduction of phytohemagglutinin, which allowed chromosome preparations to be made within 2–3 days from peripheral blood samples (11). This reagent was originally used to clear red cells from preparations of lymphocytes, but it was found that T lymphocytes underwent transformation and division under its influence. When colchicine was used to accumulate lymphocytes in metaphase during short-term culture, air-dried drop preparations of metaphase chromosomes could be made far superior to any previous method. The simplicity of the technique, which is still in use almost unchanged, has undoubtedly been responsible for the widespread application of chromosome analysis throughout the world and for the growth of human cytogenetics as a diagnostic procedure in clinical medicine. In the 1960s, individual chromosomes were identified by characteristics such as total length, centromere index (length of short arm divided by total length), the presence of heterochromatic regions, and the pattern of DNA replication as revealed by pulse labeling with tritiated thymidine. These studies revealed considerable normal variation in chromosome size and centromere position, much of which was

heritable and of no clinical significance. Only chromosomes 1, 2, 3, 9, 16, and the Y chromosome could be identified with certainty in any one metaphase by standard techniques. Chromosomal heteromorphisms mainly involved the centromeres of chromosomes 1, 9, 16 (and occasionally chromosomes 3 and 4); the short arms and satellites of chromosomes 13, 14, 15, 21, and 22; and the distal heterochromatic region of the long arm of the Y chromosome.

Because of the limited availability of testicular biopsies and the virtual lack of access to ovarian tissue, meiotic chromosome analysis has contributed comparatively little to human cytogenetics and to the diagnosis of chromosome aberrations. However, much has been learned about the behavior of human chromosomes in meiosis, about the identification of bivalents at pachytene (especially the nucleolar chromosomes), about the pairing of chromosomal rearrangements, about the number and location of chiasmata, and about the extent of homologous and nonhomologous pairing of the X and Y chromosomes. Although the morphologic aspect of meiosis has been well studied, much has still to be learned about the biochemistry of synapsis, recombination and chromosome segregation.

In 1970 two new techniques were introduced that have had a major impact on modern cytogenetic analysis. The first was the demonstration by Pardue and Gall (12) that isotopically labeled DNA probes could be annealed to complementary DNA sequences in cytologic preparations of chromosomes made by standard techniques, a procedure referred to as *in situ* hybridization (ISH). Pardue and Gall also noted that when the denatured chromosomes were stained by Giemsa, the paracentric regions were preferentially stained (C bands, see later). Various modifications of the denaturing and staining process by other workers following Pardue and Gall yielded chromosomes that showed patterns of differential staining along their length, which appeared specific for each chromosome. These experiments were extended and led to the second major development, the establishment of a standard chromosome banding pattern, and this has become the criterion for chromosome identification and classification in many species.

Even before chromosome denaturation was being used to produce various banding patterns, Caspersson et al. independently discovered that quinacrine compounds that intercalate in DNA could produce bright fluorescent bands visible along the chromosome using fluorescence microscopy (13). The quinacrine bands (Q bands) were at first more reproducible than those produced by denaturing and Giemsa staining but yielded virtually the same banding pattern and were equally useful for chromosome identification.

Cytogenetic analysis has evolved from these beginnings, the main ingredients being cell culture, colchicine treatment to accumulate metaphases, manipulations of the cell cycle to enhance chromosome morphology,

hypotonic treatment to separate the chromosomes from one another, fixation in suspension followed by air drying, banding methods for chromosome identification, and *in situ* hybridization for the localization of specific DNA sequences. The growing emphasis on timely management of patients and the detection of chromosome abnormalities beyond the resolution of the light microscopy in recent years has led to the development of targeted molecular cytogenetic techniques freed from the cell culturing and lengthy protocols used for the preparation of high-quality metaphase spreads. These new technological advances allow quantitative evaluation of the chromosomal content and include methods such as quantitative FISH and polymerase chain reaction (Q-PCR), comparative genomic hybridization (CGH) and array-CGH, multiplex amplifiable probe hybridization (MAPH) and multiplex ligation-dependent probe amplification (MLPA). These methods allow higher resolution chromosome analysis and at the same time are more amenable to automation and high throughput of the samples than traditional methods.

FISH-based techniques provided a bridge between the chromosomes, as viewed under the microscope, and the DNA that comprises the chromosomes. FISH vastly improved our ability to diagnose small aberrations and characterize marker chromosomes not identifiable by banding. FISH was introduced to cytogenetics in the mid-1980s, just as the field of molecular biology was being revolutionized by advances in DNA analysis, most spectacularly, the PCR. As the human genome project progressed through the 1990s, more and more FISH probes became available, increasing our power to diagnose clinically recognizable syndromes. In general, FISH studies are limited by the need to know which region of the genome should be analyzed (disease-related critical regions, specific chromosomes) and cannot be used to survey the entire genome at high resolution. A partial exception to this was the development of a subtelomere assay, in which the subtelomeric regions of all of the human chromosomes were analyzed sequentially in one assay. The subtelomeric probes were developed in response to the hypothesis that polymorphisms in human telomeric region are more prone to breakage and reunion and could play a role in cryptic translocation events that underlie a significant percent of human pathology (14). As probe sets containing probes for each of the human subtelomeric regions became available, they were used in screening cohorts with varying criteria (mental retardation, with and without dysmorphic features, other congenital anomalies, family history of related abnormalities), and varying but significant percentages of patients with sub-telomeric imbalances were identified, ranging from 3% to 29% (15,16).

CGH was the next major advance in genomic analysis, and provided a tool to determine the amount of DNA in specific genomic regions (thereby diagnosing deletions or duplications) on a molecular level. Initial methods

allowed comparison of DNA content from a patient, with a normal control, by fragmenting the two genomes, labeling test subject and control with fluorescent dyes of different wavelengths, and co-hybridizing to chromosomes from a normal individual. The ratio of fluorescence of the two colors is measured along the length of each chromosome, and relative gains or losses were recorded as deviations from the 50:50 mixture anticipated if the test subject is normal (17). Since this technique utilizes DNA, there is no need to culture cells, which is an advantage in analysis of tumors or in any case where living tissue is not available. The resolution of CGH done in this fashion, however, was not higher than that of analysis of metaphase chromosomes when applied to constitutional cytogenetics. Nevertheless, CGH paved the way for array-based CGH, in which DNA from patient and control is co-hybridized against DNA that has been spotted on an array (2). With array-CGH, the choice of which clones to place on the array lies in the hands of the investigator and can range from selected clones covering specific regions of the genome to a tiling path of the entire genome. The array can utilize large pieces of DNA such as inserts of human DNA into bacterial artificial chromosomes (BACs), smaller DNA fragments (oligonucleotides) or can utilize polymorphic regions of the genome such as single nucleotide polymorphisms (SNPs). The use of high-resolution arrays is presenting unique opportunities to explore changes in DNA copy number in both health and disease. Both array-CGH and SNP array analysis have surprisingly identified a significant fraction of the genome that can vary in copy number between apparently healthy individuals (3,18–22). The current challenge in the cytogenetics/cytogenomics laboratory is to incorporate these technological advances to identify clinically significant copy number alterations, while avoiding the copy number alterations that are true polymorphisms.

### 22.3 THE INDICATIONS FOR CYTOGENETIC ANALYSIS

The history of human cytogenetics over the past 55 years has been punctuated by the introduction of new technology followed by the identification of increasing numbers of aberrations, smaller in extent and often associated with less striking phenotypic changes. The indications for cytogenetic analysis have thus widened over the years. For example, the occurrence of a monogenic disorder associated with mild mental handicap may indicate the presence of a microdeletion detectable by array-based analysis or of DNA disruption at one of the breakage sites of a reciprocal translocation. A list of general indications for cytogenetic analysis includes the following:

1. Confirmation or exclusion of the diagnosis for known chromosomal syndromes.
2. Unexplained intellectual disability or developmental delay with or without dysmorphic features.

3. Autism spectrum disorders.
4. Congenital anomalies.
5. Abnormalities of sexual differentiation and development.
6. Infertility/subfertility.
7. Recurrent miscarriages or stillbirth.
8. Pregnancies shown to be at risk of aneuploidy from the results of maternal serum screening or fetal ultrasound scanning.
9. Neoplastic conditions for which the identification of specific chromosomal aberrations may be valuable in diagnosis and management.

Full descriptions of the main chromosomal syndromes are given in Chapters 43–45.

### 22.4 TISSUE SAMPLES AND CELL CULTURE

Chromosome preparations for cytogenetic analysis are made from dividing cells, either directly from tissue samples (e.g. bone marrow, testis, chorionic villi, neoplastic tissue) or after cell culture (biopsy of skin or almost any other living tissue including amniotic fluid cells). Tissue preserved in a fixative is not suitable for making conventional chromosome preparations. It is imperative to use the correct sterile containers when sending biopsy and other tissues to the cytogenetics laboratory to ensure that the cells remain viable and suitable for cell culture. Paraffin-embedded tumor tissue sections can be “FISHed” for deletions/amplification of tumor suppressor genes and oncogenes to assist in diagnosis, prognosis, and management after therapy.

For array-based techniques, dividing cells are not necessary, and all that’s needed is a source of DNA. This can come from peripheral blood or tissue samples and techniques are improving to obtain the DNA from paraffin-embedded tissue sections.

### 22.5 CHROMOSOME BANDING

For identification of normal chromosomes and detection of aberrations, the air-dried chromosome preparations must be stained appropriately. Chromosome banding refers to alternating light and dark regions along the length of a chromosome, produced after staining with a dye. A band is defined as the part of a chromosome that is clearly distinguishable from its adjacent segments by appearing darker or lighter with the use of one or more banding techniques. The fluorescent dye quinacrine was used to produce the first banding patterns as mentioned above (Q-banding), and through the years several general banding stains, as well as several techniques for staining specific parts of the genome have been used. Generalized banding techniques have included Q-banding, Reverse (R) banding and G-banding. Specific staining protocols include C-banding and staining

of the nucleolar organizing regions (NORs) using a silver stain (Ag-NOR). G-banding is the benchmark for the routine analysis of human chromosomes, producing a characteristic light and dark banding pattern along the chromosomes (Figure 22-1). Each chromosome has a unique sequence of bar code-like stripes, allowing identification of individual homolog and the analysis of abnormalities of their structure by disruption of the normal banding pattern. Many methods have been published for the production of G bands, but most of them rely on proteolytic digestion of the chromosomes by trypsin followed by staining with either Giemsa or Leishman stain. Little is known of the precise nature of the mechanism of G-banding despite much conjecture. The dark bands contain mainly A–T rich DNA, and the light bands are G–C rich. Manipulation of the cell cycle to produce prometaphase chromosomes with resolution of >550 G-bands per haploid set provides a mechanism for high-resolution analysis of the structure of the chromosomes.

## 22.6 THE NORMAL HUMAN KARYOTYPE

Each species has a chromosome complement, characteristic in number and form. This is known as the karyotype, and the name is also used for a photographic preparation in which the stained chromosomes are arranged approximately in order of decreasing length. Conventional banding allows each normal human chromosome to be given its specific identity number. To make analysis easier, the banding pattern can be diagrammatically represented in the form of an idiogram (Figure 22-2). About 400 distinct bands per haploid complement usually may be visible in any one metaphase preparation. In prometaphase cells, more than 550 bands may be resolved because the chromosomes are more extended. The International System for Human Cytogenetic Nomenclature (ISCN) was established in 1978 by a standing committee to provide a simple shorthand, based on the human banded

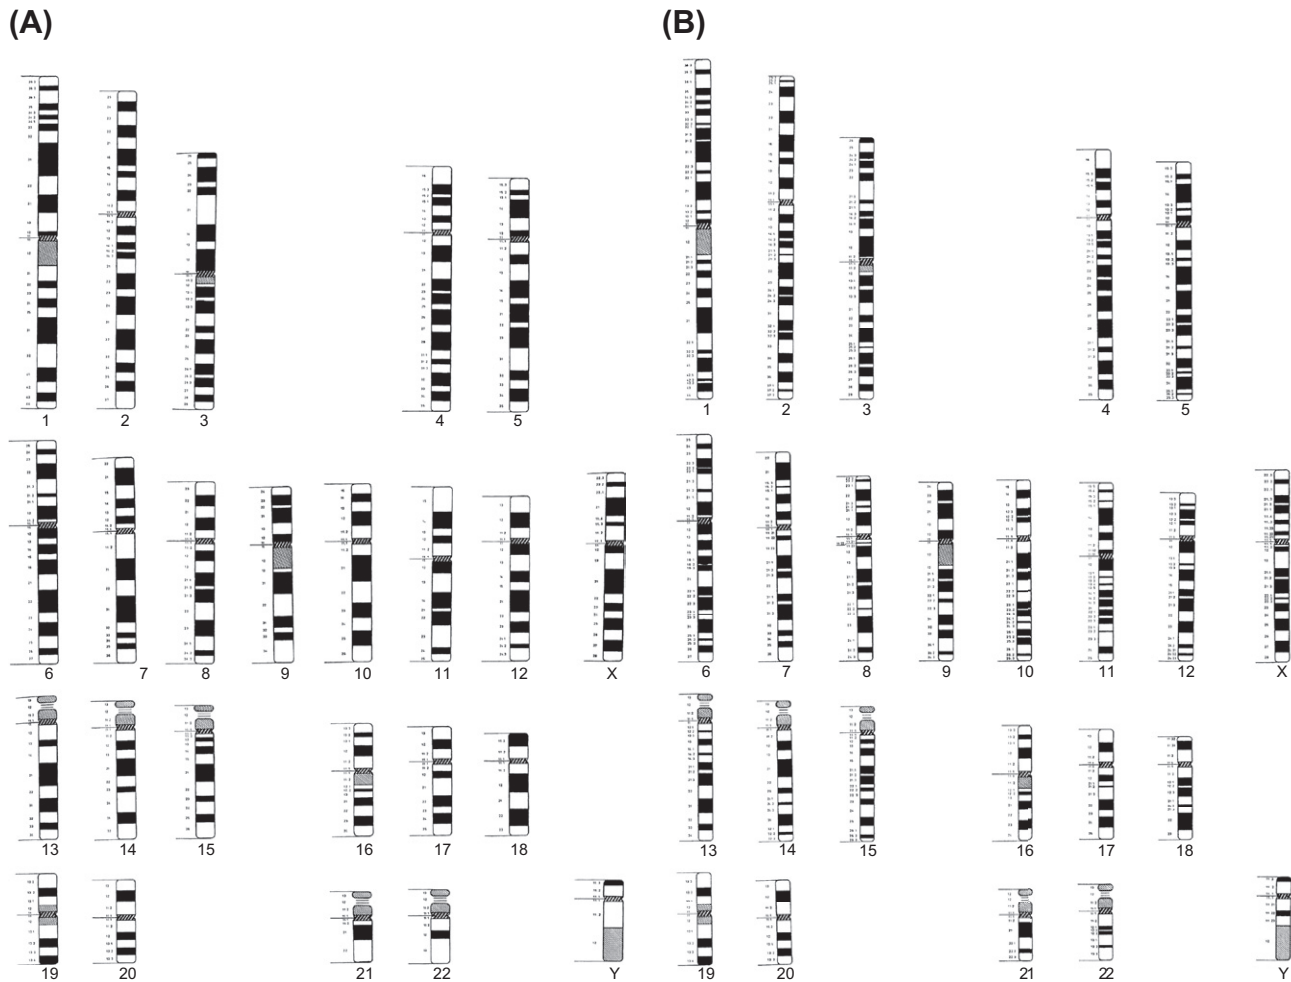

idiogram, to describe any given chromosome aberration and the karyotype of any individual (24). In this nomenclature, which has been updated regularly, the number of chromosomes in the karyotype is given first, then the sex chromosome constitution, followed by a shorthand description for any abnormal chromosome. Thus, 46, XY is a normal male karyotype, and 47, XX, +21 is the karyotype of a female with Down syndrome. Parts of chromosomes or sites of chromosome rearrangement are identified using a simple numbering system specific for each chromosome band or sub-band. In this description, the chromosome identifier is given, followed by the designation for the chromosome arm, p (petit) for the short arm and q for the long arm, and then the number of the chromosome band involved in the rearrangement. The main landmarks of each chromosome are the centromere, cen, and the end of the arm, pter for the short arm and qter for the long arm. The most striking of the bands are the remaining landmarks, and these divide the arm into distinct regions. Each region is further subdivided into bands and sub-bands. Thus, band Xp21.2 is to be found in the short arm of the X chromosome in region 2, band 1, and sub-band 2. The shorthand for the exchange of chromosome fragments between 7p21.2 and, for example, 9q34.1 in a female individual would be given as 46, XX, t (7;9) (p21.2;q34.1), where t, translocation and the semicolon is used to separate the chromosomes and break points. These and other symbols used are listed in Table 22-1. The ISCN provides nomenclature to describe constitutional and acquired chromosome abnormalities and fluorescence in situ hybridization studies (further details of ISH nomenclature are given in the FISH section) (25). Examples of the use of the shorthand are given in the following section where the classification of chromosome abnormalities is considered.

Chromosome analysis in normal individuals has revealed substantial variation in the karyotype that is without phenotypic effect. It is important to recognize and distinguish this normal variation from the abnormal chromosomal rearrangements that are clinically significant. The most striking of these variations, or heteromorphisms, occur at the centromeric regions of chromosomes 1, 9, and 16, at the short arms of chromosomes 13, 14, 15, 21, and 22, and at the distal end of the long arm of the Y chromosome. All these regions contain variable amounts of highly repetitive DNA (satellite DNA) composed largely of tandemly arranged repeats that are not transcribed. Unequal crossing-over within these repeats during meiosis may account for the variation, but this must occur rarely, because extreme examples of these heteromorphisms are invariably transmitted unchanged in pedigrees. Several euchromatin heteromorphisms have also been described that may present a specific diagnostic concern, particularly when detected at prenatal diagnosis or in an individual with an abnormal phenotype. Euchromatic variants at chromosomes 8p23.1, 9p12 and qh, 15q11.2, and 16p11.2 have been characterized on

**FIGURE 22-1** G-banded metaphase with three marker chromosomes (whose origin from chromosomes 22, 11, and 14 cannot be identified by this technique).

**FIGURE 22-2** Human idiogram based on G-banding pattern and showing the banding nomenclature according to the International System for Human Cytogenetic Nomenclature (23). (A) Approximately 400 of the main G bands per haploid complement are shown, as seen in most banded metaphase preparations suitable for cytogenetic analysis. (B) Approximately 550 G-bands per haploid complement are shown, as seen in early metaphase preparations.

a molecular level and found to comprise region-specific pseudogene cassettes containing processed paralogous sequences frequently dispersed/transposed to/from pericentromeric or protelomeric sites (26–29).

## 22.7 CHROMOSOME ABNORMALITIES

Genetic mutations involve duplication, deletion, or rearrangement of DNA. The extent of the change varies from the gain or loss of a single nucleotide (a point mutation) to gain or loss of whole chromosomes. When the field of genetic analysis relied on either chromosome analysis or DNA analysis, those changes that were large enough to be detectable under the light microscope were classified as chromosome aberrations, but they differed from molecular mutations involving individual genes only in terms of scale. Molecular techniques generally involve analysis of single genes, and focus on mutations that are intragenic, while cytogenetic methods revolve larger genomic alterations affecting multiple genes. With the introduction of increasingly

sensitive techniques into the cytogenetics laboratory, we are able to diagnose single gene deletions, or intragenic deletions or duplications, and the divisions between the cytogenetic and molecular diagnostics are blurring. Historically, it has been possible to identify genomic deletions or duplications that are a minimum of 5–10 Mb by cytogenetic techniques, although there are many cases where even deletions or duplications slightly greater than 10 Mb were missed by analysis of banded chromosomes. Array-based techniques provide resolution that is much finer, and some arrays can diagnose single exon changes (30). Currently, many laboratories use standard cut offs of 100–200 kb for diagnosis of deletions, and 500 kb to 1 Mb for duplications. There are several chapters in this book that deal with the specifics of chromosome abnormalities including Trisomy and triploidy (Chapter 43), structural chromosome abnormalities such as translocation (balanced or unbalanced), Robertsonian translocations, isochromosomes, insertional translocations, deletions, duplications, inversions, marker chromosomes and

**TABLE 22-1 The International System for Human Cytogenetic Nomenclature (ISCN) Nomenclature: Symbols and Abbreviations Used for Describing Chromosome Aberrations**

Symbol	Definition
p	Short arm
q	Long arm
pter	Terminal of short arm
qter	Terminal of long arm
cen	Centromere
h	Heterochromation
add	Additional material of unknown origin
del	Deletion
der	Derivative of a translocation
dic	Dicentric
dup	Duplication
fra	Fragile site
i	Isochromosome
isodic	Isodicentric
inv	Inversion or inverted
r	Ring chromosome
rec	Recombinant from inversion or insertion
t	Translocation
upd	Uniparental disomy
mat	Maternal origin
pat	Paternal origin
mar	Marker chromosome of unknown origin
dir	Direct as opposed to inverted
::	Breakage with reunion
/	Mosaicism (separates clones)
+/-	Before a chromosome number, indicates gain or loss of that chromosome
;	Separates altered chromosomes and break points involved in structural rearrangements—indicates from and to

ring chromosomes (see Chapter 45). As techniques for cytogenetic analysis have evolved, the types of chromosome abnormalities that are detectable have changed as well. Initially, only larger abnormalities such as gain or loss of an entire chromosome or large alterations visible on banding could be diagnosed.

## 22.8 IN SITU HYBRIDIZATION

The ISH technique is based on the principle that when double-stranded DNA is heated, it denatures into single-stranded DNA. On cooling, the single-stranded DNA reanneals with its complementary sequence into double-stranded DNA. If an appropriately labeled DNA sequence (probe) is denatured and added to denatured nuclei, or chromosomes during the process of reannealing, some of that labeled DNA will hybridize to its complementary sequence in the chromosomal DNA. Detection of the labeled DNA will identify the site of hybridization and thus the region of chromosomal DNA complementary to the DNA sequence in the labeled probe. Thus, ISH

may be used to map and order genes and other DNA sequences along the length of a chromosome.

In the early days of ISH, DNA probes were labeled with radioisotopes, such as tritium ( $^3\text{H}$ ) or radioactive iodine ( $^{125}\text{I}$ ), and detected by autoradiography using photographic emulsion applied directly to the microscope slide. The scatter of radioactive disintegrations, revealed by silver grains in the developed emulsion, meant that the resolution was poor. The autoradiographs often had to be exposed for several weeks to achieve an adequate signal; therefore it was not possible to tell whether the probe had hybridized satisfactorily until long after the experiment had been set up. These disadvantages, coupled with the hazards of radioisotopes and the need to count silver grains in a large number of cells to establish significant counts above background levels, led to the search for nonisotopic methods of labeling.

In situ hybridization was used first to map the chromosomal location of highly repetitive (satellite) DNA to the centromeric regions of mouse chromosomes and the moderately repetitive ribosomal DNA to the nucleolus organizing regions in the polytene chromosomes of *Diptera* (12). Similar studies soon located these repetitive DNAs to the equivalent sites in human chromosomes (31). However, it was not possible to incorporate sufficient radioactivity in probes derived from single-copy DNA sequences to permit the more extensive application of ISH in gene mapping. This had to await the introduction of recombinant DNA techniques and the development of DNA sequences cloned in plasmids that could be heavily labeled. The early 1980s saw the first chromosomal localizations of single-copy DNA sequences by ISH, and ISH soon became the method of choice for assigning a cloned DNA sequence to its position in the chromosomal map (32–34). It was quickly appreciated that ISH also had application in diagnostic cytogenetics, particularly for the detection of structural abnormalities beyond the resolution of conventional banding techniques.

The search for nonisotopic alternatives for labeling probes for ISH led first to the introduction of biotin and then other haptens including acetylaminofluorene and digoxigenin (23,35–38). Biotin and digoxigenin have proved the most useful, and a variety of methods have been developed to detect both these labels in cytologic preparations using fluorescence or enzyme-linked reactions.

Almost all types of DNA probe used in FISH applications in diagnostic cytogenetics contain interspersed repetitive elements that will hybridize to complementary sequences throughout the entire genome leading to a high level of background signals. This background can be suppressed effectively by preannealing unlabeled genomic or Cot-1 (enriched for highly repetitive sequences) DNA to the labeled probe before hybridizing the probe to the target DNA (39). The unlabeled DNA acts as a competitor and will form duplexes rapidly with the repetitive DNA sequences within the probe. The low-copy DNA remaining in the probe will then be available to hybridize with

complementary sequences in the target DNA. With many DNA probes, the use of Cot-1 DNA may be avoided by allowing the probe to preanneal with itself before application to the target.

### 22.8.1 DNA Probes and Their Applications

The various classes of DNA probe have wide applications in diagnostic cytogenetics to augment conventional banding analyses of chromosomal rearrangements. When genomic analysis starts with array-based testing, FISH is often needed to obtain positional information, such as the chromosomal location of a duplicated region of the genome.

Collections of chromosome-specific painting probes (Figure 22-3) derived from each chromosome, usually by flow-sorting and less frequently by microdissection, and labeled end-to-end by nick translation or DOP-PCR, are routinely used as a screening tool in the characterization of an abnormal chromosome (40). Centromeric probes on their own and in combination with single-copy DNA sequence probes are widely used in the determination of chromosome copy number in interphase nuclei or as control probes in interphase FISH analysis (Figure 22-4). The main applications are in rapid aneuploidy tests for prenatal and preimplantation diagnosis, in characterization of marker chromosomes, and in the diagnosis of hematological cancers.

Thanks to the International Human Genome Project, a physical map of the human genome composed of a series of overlapping cloned DNA sequences along each chromosome is available in BAC vectors. These clones act as reference markers along the chromosome and are also suitable for FISH. Many other DNA sequences of interest, including sequences from known genes, have been cloned in yeast artificial chromosome (YAC) and cosmid vectors; both are suitable for FISH. YAC clones can accept inserts of up to 2 million base pairs and have the disadvantage that they may contain sequences from more than one chromosomal region (due to colligation) and seem more liable to lose parts of the insert through deletion. Cosmid clones can accept smaller inserts of up to 40kb and do not have these disadvantages. Both types of clone can be used as markers for gene loci, for the delineation of break points and for the identification of deletions and duplications associated with chromosomal syndromes. For example, cosmid clones are widely used for the diagnosis of microdeletion syndromes (see Table 22-2 and Figure 22-5) and in screening for subtelomeric chromosomal imbalances (Figure 22-6) found in 5–10% of patients with dysmorphic features and developmental delay (16,41–43). Today, many large cytogenetic laboratories have access to a bank of clones that represent sequences covering the whole genome with a resolution of up to 1Mb to allow more precise characterization of different chromosomal abnormalities.

Multicolor clone sets for the detection and monitoring of critical genetic aberrations associated with

Note Y signal on XY homologous regions of Xp (tip) and Xq (proximal third) and X signal on XY homologous region of Yp (tip).

hematopoietic disorders are widely used for the analysis of uncultured bone marrow samples and tumor tissue biopsies. Hybridization targets of these DNA probes have been designed to flank or span common translocation break points on one or both rearranged chromosomes, thus resulting in characteristic signal

(C) As above, from male fetus with trisomy 21 (Down syndrome). (D) As above, from normal male fetus. (From Divane, A.; Carter, N. P.; Spathas, D.H.; Ferguson-Smith, M. A. *Rapid Prenatal Diagnosis of Aneuploidy from Uncultured Amniotic Fluid Cells Using Five-Color Fluorescence in situ Hybridization*. *Prenat. Diagn.* **1994**, 14, 1061–1069, with permission.)

pattern in normal and abnormal cell populations. The probes most commonly used in the diagnosis and monitoring of hematological malignancies are centromeric probes, dual and single fusion probes (Figure 22-7A), extra signal probes, and break-apart probes. In solid tumor diagnostic enumeration, probes complementary to unique sequences of known oncogenes and cancer suppressor genes are being widely used on imprinted fresh tumor samples and paraffin-embedded tissue sections (Figure 22-7B). Recent developments in automated scanning and image capturing systems together with automated spot counting and image analysis software allow high throughput, automated interphase FISH analysis of many different sample types as well as simultaneous FISH and conventional immunofluorescence staining.

### 22.8.2 Molecular Substitutes for Multiprobe Fish Tests

Faster, cheaper, and often more precise molecular techniques are adding to an expanding set of tools in the diagnostic cytogenetic laboratories. MAPH is a method that measures copy number (dosage) variation of DNA

of almost any size. The method combines hybridization of DNA probes to target genomic DNA immobilized on a solid support. After washing, each specifically bound probe is present in an amount proportional to its target DNA copy number. All probes are then simultaneously amplified using a single primer pair and quantified after electrophoretic separation (44). MLPA shares the basic principles of primary probe hybridization with subsequent quantitative probe amplification with MAPH. Instead of probe hybridization to a filter-bound target DNA, in MLPA two adjacent complementary oligonucleotides hybridize to their target sequence in solution. One of the two oligonucleotides is cloned in an M13-derived vector that contains an inserted stuffer sequence size-specific for each probe. In the subsequent ligation step, only the adjacent oligonucleotides hybridized to their target DNA sequence are ligated. As in MAPH, the ligation-generated template is suitable for PCR amplification using a single primer pair. After the electrophoretic separation that identifies each probe, the PCR products are quantified by comparing the peak areas of the amplification products to a set of amplified controls or to neighboring peaks (45).

DMD, Duchenne muscular dystrophy; WAGR, Wilms' tumor, aniridia, genitourinary abnormalities and mental retardation.

Both methods allow reliable screening for DNA copy number changes at ~40 loci simultaneously, and both methods are being used in various diagnostic applications, including screening for subtelomeric deletions/duplications and unbalanced cryptic telomeric translocations, aneuploidies, whole or partial gene duplications, or deletions (29,45–48).

### 22.8.3 DNA Fiber-FISH

Because of the condensation of the chromosome fiber at metaphase, the fluorescent signals from two cosmid clones hybridized to the same chromosome can be resolved only if they are more than 2–3 Mb apart. Because the chromosomes are 10 times more extended in hypotonic preparations of interphase nuclei, the resolution at interphase is much better, and two cosmids

more than 50kb apart can usually be distinguished from one another (49). The order of several closely linked cosmids may be determined at interphase, provided they are more than 50kb and less than 1 Mb apart (50). The latter restriction is due to the tendency of a chromosome to coil back on itself and because the chromosome fiber forms loops radiating in all directions from the central chromosome scaffold. Various techniques have now been developed that release the chromosome fiber from its associated protein within the chromosome scaffold (51–53). This permits DNA sequences to be hybridized directly onto extended chromosome fibers fixed on a microscope slide and analyzed by FISH (Figure 22-8). The resolution of this technique is astonishing; sequences less than 5 kb apart can be separated readily, and distances down to 1 kb have been claimed (54).

**FIGURE 22-5** The diagnosis of microdeletion syndromes using labeled cosmid clones (ONCOR, Gaithersburg, MD) that map into the region involved in the deletion. (A) Miller–Dieker syndrome. Chromosome 17 identified by cosmid clone in 17q. Note loss of signal at 17q13 in one homolog (right). (B) Williams syndrome. Chromosome 7 identified by cosmid clone at distal end of 7q. Note loss of signal at the elastin locus on 7q11.23 in one homolog (lower). (C) Prader–Willi syndrome. One homolog of chromosome 15 shows loss of signal at 15q12. (D) DiGeorge syndrome. One homolog of chromosome 22 shows loss of signal at 22q11.

**FIGURE 22-6** Human metaphase showing telomeric probes for chromosome 1p, 1q, and pairing regions of Xp and Yp. X alpha centromeric probe identifies the X centromere.

Decondensation of chromatin by detergent and salt or alkaline solutions results in the release of loops of chromatin fibers of more than 200nm in length from nuclei in air-dried fixed preparations. Typically, the chromatin loops out from the nucleus and forms a halo of DNA fibers around the nucleus. Where the loops are broken, the fibers are more extended and are seen as long thin filaments that radiate away from the nucleus. Fibers up to 10Mb long have been achieved by using agarose-embedded cells treated with proteinase K and ribonuclease. The agarose is then melted and spread onto

poly-l-lysine-coated microscope slides (55). This method seems more robust than others used for fiber-FISH.

The analysis of extended DNA fibers by FISH has application both in the mapping and ordering of contiguous DNA sequences and has been used in the detection of carriers of intragenic gene deletions in X-linked Duchenne muscular dystrophy (56).

#### 22.8.4 FISH Nomenclature

The Standing Committee for the ISCN has developed nomenclature to describe investigations and abnormalities detected by DNA probes. The observed chromosome banding is described by the standard nomenclature. This is followed by a period (.) and the abbreviation “ish,” which precedes the description of the in situ hybridization findings. The abnormality identified by ISH is described starting with the abbreviation for the type of abnormality followed, in separate parenthesis, by the chromosome(s), break point(s), and the loci for which probes were used, designated according to the Genome Database (GDB) and ordered from pter to qter. If no GDB locus is available, the name of the probe can be given instead. Capital letters are used for the locus, and “+” or “–” given immediately afterward indicates whether the locus has been identified as being present or absent, respectively. Thus, ish del (22) (q11.2q11.2) (D22S75–) indicates a deletion in the DiGeorge chromosome region, and ish dup (17) (p11.2p11.2) (CMT1A++) indicates a duplication at the Charcot–Marie–Tooth locus. If no abnormality is detected, the chromosomal location follows ish,

**FIGURE 22-7** (A) Chronic myeloid leukemia showing detection of the Philadelphia translocation using BCR/ABL dual color dual fusion probe. The ABL gene and the BCR region map to chromosomes 9 and 22, respectively, and the translocation regions are revealed by the combined signals on each derivative chromosome. (B) Amplification of HER2 (ERBB2) oncogene in paraffin-embedded section of breast cancer tissue. Centromeres of chromosome 17 are shown.

10  $\mu$ m

**FIGURE 22-8** Fiber-FISH. Decondensation of chromatin by alkali treatment of fixed nuclei and hybridization of closely linked labeled cosmid clones. Three cosmids from the HLA region (lower), FITC (middle), and a 50:50 mixture of FITC and HLA (upper), respectively. Each cosmid measures 35kb and there is a 5–10 kb gap between the different cosmids.

and the usual two copies of the probe are confirmed; for example, ish 22q11.2 (D22S75x2). The origin of a cryptic balanced translocation identified by forward painting is given as ish t(4;11) (p16.3;p15) (wcp4+;wcp11+), where wcp is whole chromosome paint. Similarly, the origin of an extra marker chromosome revealed by reverse painting is given as 47, XY, +mar.rev ish der (18) t(12;18) (p13.3;p11.2). The ish nomenclature includes symbols appropriate for interphase FISH (nuc ish) and fiber-FISH (fib ish) (25).

### 22.8.5 Comparative Genomic Hybridization

An ingenious FISH technique was developed for the cytogenetic analysis of tumor samples that is capable of

identifying DNA amplifications and deletions of around 5 Mb and the threefold to fivefold amplification of oncogenes in a single sample of tumor material (17). The method, CGH, is a development of reverse painting in which test DNA and normal genomic reference DNA are isolated, fragmented, differentially labeled (for example, in green and red, respectively), mixed and allowed to compete for hybridization sites in sets of normal high-resolution metaphase spreads. The relative amounts of test and reference DNA that anneal to a particular chromosome region will depend on the number of copies of DNA complementary to that region in the test sample. If the test sample contains relatively more of a particular DNA than the reference sample, this will be revealed by an increased green/red fluorescence ratio in the complementary region; similarly, chromosomal deletion in the test sample will be revealed by a decreased green/red fluorescence ratio. Significantly, this method uses DNA from the individual to be tested, with no need to culture cells prior to the analysis. CGH requires digital fluorescence microscopy in which the relative amounts of green and red fluorescence are measured along the length of the chromosome.

In addition to confirming the results of conventional chromosome analysis in neoplastic conditions, the CGH technique has been used to identify chromosomal regions that are recurrently lost or gained in specific tumors. CGH has also been successfully applied in constitutional cytogenetics, and in fact its use has contributed to a revolution in cytogenetic diagnostics.

### 22.8.6 Array-Based Genomic Analysis

The replacement of metaphase spreads by an array of cloned DNA sequences or PCR products offer much higher resolution and more precise information on the break points of rearranged chromosomes than does conventional metaphase CGH (2,57). Moreover, each clone and PCR product spotted on an array has known

## ARRAY-COMPARATIVE GENOMIC HYBRIDIZATION

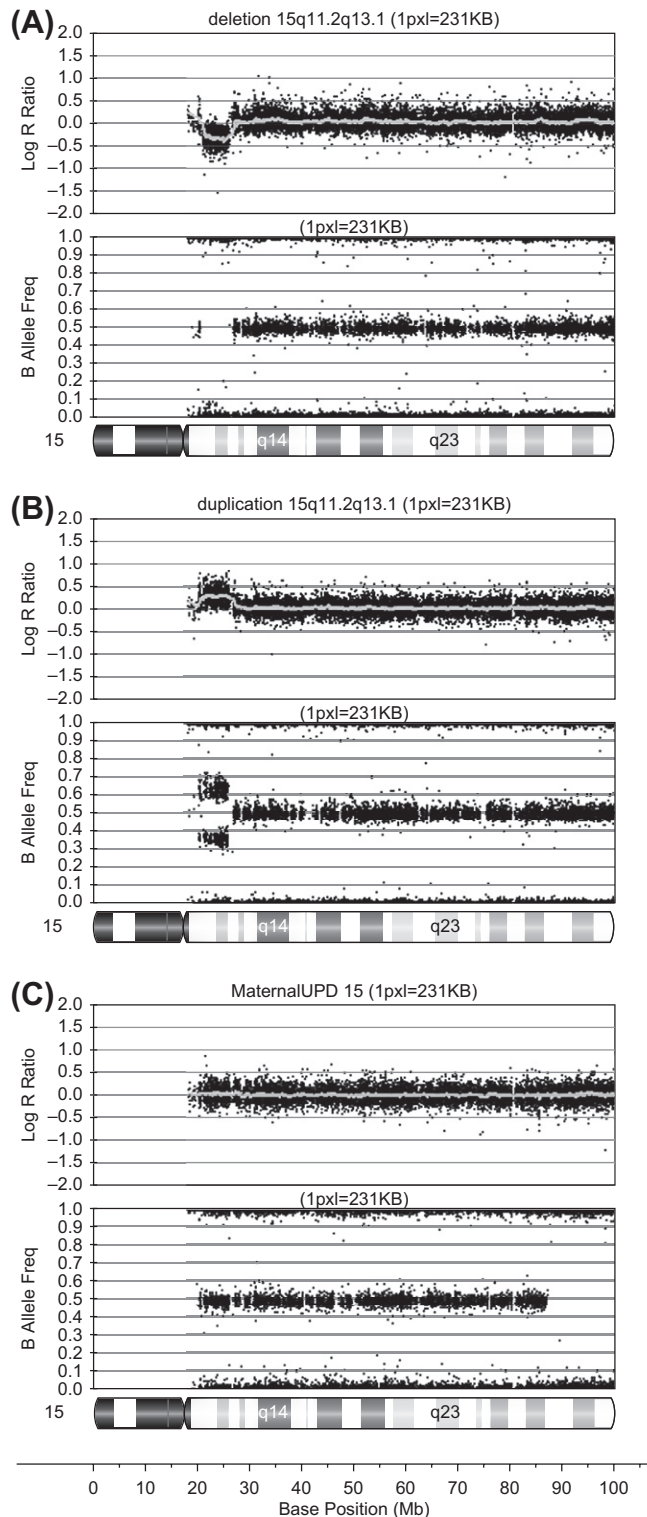

**FIGURE 22-9** Array-CGH analysis in a patient with epilepsy and moderate mental deficiency revealing a cryptic duplication of chromosome 11 short arm. Total labeled genomic DNA from patient is co-hybridized with labeled control DNA and unlabeled Cot-1 DNA to an array platform containing approximately 3000 characterized fragments selected from across the human genome. In two experiments using alternative labels for patient and control DNA, the fluorescence ratio is measured for each DNA spot on the array and plotted on chromosome-specific ratio profiles. Significant deviations from the expected 1:1 for a given DNA fragment indicate a change in copy number for that particular sequence in the patient with respect to the control. True copy number changes are seen as symmetrical deviations from the 1:1 axis in both experiments. The remaining chromosome profiles appear normal with the exception of occasional large-scale copy number polymorphisms (35).

sequence and contains known genes and other expressed sequences, facilitating precise genotype–phenotype correlations and consequently targeted patient management. Initially CMA was performed using relatively large insert DNAs from BACs, but the technology has evolved with initial utilization of shorter inserts from cosmids or fosmids to utilization of single-stranded oligonucleotides, ranging in size from 20 to 70 bp (Figure 22-9). Currently, the most commonly used platforms utilize oligonucleotides, SNPs or a combination of the two (58).

SNP arrays differ from oligonucleotide-based arrays in that they capture genotyping information in addition to copy number information. SNP arrays were originally developed for genotyping applications, but it subsequently became clear that they could also reveal genomic copy number information. The genotyping information provided by the SNP array expands the types of abnormalities that can be detected to include detection of regions of homozygosity (which could indicate either uniparental disomy or regions that are identical by descent). This allows diagnosis of imprinting disorders,

**FIGURE 22-10** Genome-wide SNP array results for individuals with three different abnormalities of chromosome 15 (deletion, duplication and uniparental disomy). Each panel shows the log *R* ratio (demonstrating SNP signal intensity) and B allele frequency. The B allele frequency indicates genotypes for the bi-allelic SNPs on the array at each locus, with one allele labeled as A and the other as B. Therefore BB has a B allele frequency of 1 (2/2 alleles are B); AB has a frequency of 1/2, and AA has a frequency of 0. Chromosome 15 ideogram lies below each patient result. Panel A shows a patient with a deletion of proximal 15q showing the decreased Log *R* ratio and the loss of heterozygosity within the deletion. Panel

which were previously undetectable in the cytogenetics laboratory. In addition, utilization of SNP arrays permits diagnosis of low-level mosaicism, chimerism and incest (59) (Figure 22-10).

CMA began to be used by clinical laboratories in 2003 and over the next few years it became clear that the technology could identify genomic alterations that were likely to be causative in from 5% to 15% of individuals who had previously had a normal karyotype (60). This huge success has resulted in almost universal adaptation of CMA and in 2010 it was recommended that CMA be used as the first tier in clinical diagnostic testing, based on its increased sensitivity (4).

The primary challenge of the clinical utilization of CMA emerged in 2004, with the discovery that deletions and duplications including genes were found in individuals without any known clinical problems (controls). These deletions and duplications have been called copy number variants or CNVs. In fact the total number of genes in a healthy individual can vary by more than 100 genes. Therefore it is crucial to distinguish benign CNVs (deletions or duplications) from pathogenic. Pathogenic variants are those that are not seen in the normal, control population, and are expected to contain gene or DNA sequences that cause disease when deleted or duplicated. Conversely, benign variants are genes that are not dosage sensitive, and therefore are found to vary in the normal population. To aid in this, data from a wide variety of studies has been collected and curated in public databases, such as the Database of Genomic Variants (<http://projects.tcag.ca/variation/>). As our collective experience with CMA increases, so will our ability to interpret the data that is generated. But despite the challenges, the success of CMA in diagnosis of clinically significant genomic alterations has been spectacular. Many new syndromes have been described that are caused by deletions or duplications (e.g. 16p11.2 17q21.3 deletion) that were previously undetectable by cytogenetics or FISH, and the more common of these are described in Chapter 45.

### 22.8.7 Array Nomenclature

The Standing Committee for the ISCN has developed nomenclature to describe investigations and abnormalities detected by chromosomal microarray analysis. A normal female characterized by array testing is indicated

B shows a patient with a duplication of proximal 15q demonstrating the increased log *R* ratio and the additional genotypes in the duplication (BBB, ABB, AAB and AAA). Panel C shows a patient with uniparental disomy for chromosome 15, with heterodisomy across much of the long arm and isodisomy toward the telomere, from base position ~85 Mb (at band 15q26.1) to qter. Note, the region of heterodisomy was confirmed by comparison of the patient with parental genotypes, as it cannot be proven by the SNP array alone, although the region of isodisomy at the telomeric end raises suspicion for UPD of the whole chromosome.

arr(1–22),(X)x2, while a male is arr(1–22)x2,(XY)x1, the difference being the relative number and type of sex chromosomes. In the case of deletions or duplications, the aberration can be specified precisely, by presentation of the cytogenetic band location, followed by specification of the genomic nucleotides. For example, an interstitial deletion of the short arm of chromosome 20 might be arr 20p12.2(10,454,698–10,818,327)x1. This specifies a 323,630 bp (324 kb) deletion within 20p12.2. It is important to include information on which build of the human genome is being referenced, as the coordinates change from build to build. This should be included in the body of the report. Note that array studies by themselves do not provide any further positional information regarding the imbalance. This deletion could be associated with a translocation, for example and the only way to determine this would be to carry out accompanying chromosome or FISH analysis. SNP arrays can also identify uniparental disomy, and this can be indicated using the abbreviation upd, and homozygosity can be indicated using hmz. Inclusion of the genomic coordinates for each of these abnormalities allows the laboratory or physician to go to the genomic databases to determine the precise gene content of the deletion or duplication.

## ACKNOWLEDGMENTS

We would like to thank Dr Laura Conlin for preparing the figure illustrating the SNP arrays and Laura D Leonard for help with the preparation of the manuscript. We are grateful to Patricia O'Brien, Fengtang Yang, Willem Rens et al. from the Human Molecular Cytogenetics Group at the Centre for Veterinary Science and Lionel Willatt, Howard Martin et al. from the East Anglian Regional Genetics Department for help with preparing the illustrations and for many helpful discussions.

### Biographies

**Nancy B Spinner, PhD** is the Evelyn Willing Bromley Professor of Pediatric Pathology and Director of the Clinical Cytogenomics Laboratory at The Children's Hospital of Philadelphia, and a Professor of Pathology and Laboratory Medicine at the Perelman School of Medicine at The University of Pennsylvania School of Medicine. She received her PhD training at The University of California at Berkeley, and her Fellowship Training in Cytogenetics at The Children's Hospital of Philadelphia. Her research interests are in the identification of the genetic etiology of Pediatric Disease, and her laboratory has made contributions to understanding the genetics of Alagille syndrome, Biliary Atresia and the Ring Chromosome 20 syndrome in particular. She serves on the Scientific Advisory Board of the Alagille Syndrome Alliance, and is on the Editorial Board of Human Mutation and PLoS Genetics. She has received multiple teaching awards at The University of Pennsylvania, and a Faculty Mentoring Award from the Children's Hospital of Philadelphia.

**Malcolm Ferguson-Smith, PhD** is currently a Research Professor in the Department of Veterinary Medicine, University of Cambridge, UK. He was a Fellow in Medicine at Johns Hopkins in 1959 and he remained there working on chromosomes for nearly 3 years. During this time he established the first chromosome diagnostic service in the USA and undertook cytogenetic research into the Turner syndrome. Returning to Glasgow University in late 1961, he was appointed successively as Lecturer, Senior Lecturer and Reader before becoming Burton Professor of Medical Genetics in 1973. In 1987, he was appointed as Professor and Head of Pathology at Cambridge University and Director of the East Anglia Regional Genetics Service. On retiring from the headship of Pathology in 1998, Professor Ferguson-Smith and his research team moved to the Department of Veterinary Medicine, to establish the Cambridge Resource Centre for Comparative Genomics. He was elected Fellow of the Royal Society of Edinburgh in 1978 and the Royal Society of London in 1983. In 1980, he became the founding editor of Prenatal Diagnosis. With JM Connor his undergraduate textbook "Essential Medical Genetics" has run to five editions.

**David H Ledbetter, PhD, FACMG**, is Executive Vice President and Chief Scientific Officer at Geisinger Health System. He came to Geisinger from Atlanta's Emory University School of Medicine where he was the Robert W Woodruff Professor and Director of the Division of Medical Genetics in the Department of Human Genetics. Dr Ledbetter previously held academic and leadership positions at the University of Chicago, the National Center for Human Genome Research (now NHGRI) at NIH and Baylor College of Medicine. He is a graduate of Tulane University and earned his doctorate at the University of Texas-Austin. After his early discovery of the genetic cause of Prader-Willi syndrome and Miller-Dieker syndrome, Dr Ledbetter has focused his research efforts on discovering the underlying etiology of childhood developmental disabilities such as autism, and the translation of new genomics technologies into clinically useful genetic tests for early diagnosis and intervention. His current research interest includes leveraging the massive amount of genomics data generated during routine patient care for knowledge generation and integration of this information into electronic health records in a clinically useful manner.

### 23.1 INTRODUCTION

There can be no question that we are in the midst of a revolution in clinical medicine, as profound in its own way as the early revelations of human anatomy and physiology and the germ theory of disease. The twenty-first century has already been christened the age of molecular medicine—the molecule in question being, of course, DNA. Molecular biology, which came to dominate basic life sciences research over the second half of the twentieth century, has now become firmly ensconced in clinical medicine as well. The development of robust technologies such as the polymerase chain reaction (PCR) and massively parallel DNA sequencing and the extraordinary productivity of the Human Genome Project in elucidating medically relevant targets for these techniques have firmly established patient DNA as a powerful “analyte” in the clinical laboratory and a valid substrate for therapeutic manipulation in the clinic.

While all areas of medicine have been impacted by these developments, it is medical genetics, the specialty most directly connected to the human genome, that is the first discipline to be entirely transformed by them. If the promise of gene therapy continues to remain frustratingly elusive through successive editions of this book, such is not the case for gene-based diagnostics. In no other sector of medical practice does at least the question, if not always the actual execution, of molecular testing arise with virtually every patient seen. Not only is medical genetics by definition concerned with inherited alterations in the patient’s genome that are detectable in this way but much of its attention is also directed at ascertaining recessive carrier states, fetal conditions that will not be expressed until after birth, and predisposition to adult-onset disorders before they are symptomatic; such diagnoses often exhibit no other evidence of their presence than at the DNA level. For these reasons, medical geneticists and genetic counselors, as a group, tend to be significantly more facile and familiar with the applications and interpretation of molecular genetic tests than other clinicians. Nevertheless, keeping up with a field as rapidly evolving as this one, in which new techniques

and disease genes (not to mention their associated ethical and societal dilemmas) are reported every week, can be a challenge for even the most dedicated specialist. That is why close two-way communication between the clinic and the laboratory is so essential, more so in medical genetics practice than in any other.

### 23.2 INDICATIONS FOR MOLECULAR GENETIC TESTING

Molecular genetics has a unique range of indications, most of which are quite different from the uses of traditional clinical laboratory testing and even molecular biologic testing in other disease classes (e.g. infectious disease, cancer). Most notably, as mentioned earlier, these procedures are often performed on healthy people who have no other signs or symptoms of the disease being tested. Even if they are symptomatic, the assay is not directed at a discrete anatomic site, as would be the case with a DNA test for an infection or a tumor. Since genetic disorders reflect heritable mutations in the germline, the test in most cases can be performed on any accessible body fluid or tissue. The most common specimen is whole blood, although saliva, buccal swabs, dried blood spots, urine, and other specimens can be used, while amniocytes or chorionic villus samples (CVS) and, most recently, fetal DNA in maternal blood are collected for prenatal diagnosis.

The technical approaches as well as the psychosocial and ethical implications of molecular genetic tests may vary substantially depending on the reason for testing. The major indications are considered individually below.

#### 23.2.1 Diagnostic Testing

Most straightforward and least foreign to other areas of laboratory medicine are diagnostic molecular genetic tests performed on symptomatic patients. These are most often performed for diagnostic confirmation of a clinical impression, although they may also assist in differential diagnosis. In the latter regard, however, it should be kept

in mind that gene-based tests are specific for the disease gene being tested, and even closely related disorders will not be detected when testing for a single one (e.g. the DNA test for spinocerebellar ataxia (SCA) type 1 will not detect the mutations of SCA type 2). In addition, while diagnostic tests do not typically carry the heavy ethical concerns of predictive tests, the uniqueness of genetic disease comes into play here as well, such that a positive test in the proband places other blood relatives at risk.

### 23.2.2 Newborn Screening

Newborn screening, despite the name, is in a sense actually diagnostic testing performed very early in life, on large populations of infants who are not (yet) symptomatic, although the affected ones may well exhibit at least biochemical signs of the disease, which are the metabolite targets detected by the screening technology. The goal, of course, is to identify affected babies early in life so that treatment (dietary or pharmaceutical) can be initiated before irreversible damage occurs. Unfortunately, most of the classic autosomal recessive disorders screened in this setting, such as phenylketonuria and galactosemia, have so many causative mutations that molecular genetic testing would be less sensitive and far less cost-effective than testing by biochemical or enzymatic means, at least given the current state of DNA sequencing technology. For most such disorders, the molecular tests, if available, are reserved for backup confirmation of indeterminate results, for further genotype–phenotype correlation, or for identification of DNA markers that could be used by the family for prenatal diagnosis in a subsequent pregnancy. However, as DNA-based methods become more efficient with the continued evolution of microarray technologies and massively parallel sequencing, they may eventually become the first-tier approach for certain newborn screens.

### 23.2.3 Prenatal Diagnosis

While classical cytogenetic analysis remains the most commonly performed mode of prenatal diagnosis, the advent of reliable molecular techniques has opened a new world of prenatal testing for single gene defects. Even though some inborn errors of metabolism can be diagnosed by biochemical analysis of amniotic fluid, other disorders, such as muscular dystrophies, do not produce such easily accessible analytes and would require a far more invasive biopsy of the target tissue (e.g. fetal muscle) for examination of the gene product. Molecular genetic techniques in most situations obviate this need, since DNA containing the mutation of interest is readily obtainable from amniocytes or CVS specimens. However, given the time constraints of the prenatal setting, such an approach is usually not attempted unless there is prior knowledge of the identity of the parental mutation(s), at least in the case of disorders with extensive mutational heterogeneity. Needless to say, prenatal

molecular genetic testing demands meticulous technique because of the irreversible nature of the intervention provoked by the test results. A key aspect unique to this setting is the detection and avoidance of maternal cell contamination, which is especially crucial in CVS. Laboratory guidelines for addressing this phenomenon using tandem repeat polymorphisms have been published (1).

A more specialized variant of prenatal diagnosis available in certain situations is preimplantation diagnosis, involving single-cell genetic analysis (using powerful PCR techniques) performed on a blastomere biopsy of embryos produced by in vitro fertilization (IVF). Because of the difficulty and expense of the procedure, it is usually reserved for those couples who would be averse to abortion of an in utero pregnancy or who are already undergoing IVF for other obstetric or infertility indications. Even more so than for traditional prenatal diagnosis, the exact identity of the mutation in the parent (for a dominant disease) or in both parents (for a recessive disease) must be known before embarking on this involved procedure. Still, despite its formidable prerequisites, preimplantation diagnosis has been used many times for pregnancies at risk for cystic fibrosis (CF), thalassemia, and other disorders (2).

Most recently, the prospect of routine noninvasive prenatal diagnosis has emerged. After many years of trial and error at detecting fetal cells or DNA circulating in the maternal blood during pregnancy by cell sorting and PCR, the advent of massively parallel sequencing, which affords far greater sensitivity for analyzing small minority sequences within a much larger (maternal) DNA pool, has made this approach a reality. By measuring the relative amounts of sequenced fragments from the various chromosomes, Down syndrome and other trisomies can be diagnosed, and it is possible to assess the entire fetal genome in the maternal blood to test for monogenic mutations (3,4).

### 23.2.4 Carrier Testing and Screening

Carrier screening is another type of laboratory testing unique to the genetics setting. The term is most properly used to denote testing for recessive mutations in the heterozygous state in otherwise healthy individuals. It may be indicated in two quite different situations: one when an individual is at risk because of a positive family history for the disorder in question; the other when the individual is at risk by virtue of belonging to an ethnic group in which the population frequency of one or more mutant alleles is particularly high. The first application is more accurately termed carrier testing rather than carrier screening, especially when the causative mutation in the family is already known. The second application is true screening, since it is performed on an entire population without respect to family history, and the likely mutation in any one individual being tested will not be known (unless the disorder has only a single mutation, as in sickle cell disease).

To be considered a candidate for population carrier screening, a number of criteria must be met by both the disease and the testing technology. The disorder must be

frequent enough in the target population to justify the effort, expense, and attendant complexities. The natural history of the disorder must be severe and predictable enough to enable couples to make informed decisions about prenatal diagnosis and pregnancy termination. The available technology must be robust, relatively inexpensive, and capable of detecting a reasonable proportion of the possible disease-causing mutations. The options for intervention in those who test positive must be available, effective, and acceptable to the target population. In addition, the overall screening program must be of sufficient interest and acceptance to the target population to ensure cost-effective uptake. As will be seen, these criteria, or a subset of them, are not met by some of the gene targets that would otherwise appear to be the most obvious. CF carrier screening, although now in widespread practice, is still hampered by mutational complexity and phenotypic variability. Hereditary hemochromatosis, a possible target of adult presymptomatic screening, is currently in limbo because of confusion over the true penetrance of the mutations. Screening for fragile X syndrome mutations is controversial because of questions about prevalence and cutoff ranges and phenotypic implications of premutation trinucleotide expansions (5,6).

Because screening tests must be kept inexpensive in order to be cost-effective, screening strategies for disorders with mutational heterogeneity will often entail complex decisions regarding the number and type of mutations to be included in the test panel. Such debates have been waged for years in the case of CF (7). A decision must also be made as to whether molecular genetic testing, with its narrow focus on specific mutations, casts a wide enough net within the target population to justify using it in preference to biochemical or enzymatic screening methods, which are often less expensive. In the case of CF, the carriers have no biochemical abnormalities that can be ascertained, so direct mutation testing is the only alternative. In the case of Tay-Sachs disease, even though there are a limited number of hexosaminidase A mutations that account for most carriers in the Ashkenazi Jewish target population, enzymatic testing has long been preferred for population screening because of its ease of use, low cost, and ability to capture carriers with uncommon mutations. However, as screening in this ethnic group has expanded to encompass as many as 15 or more additional recessive disorders, it has become easier to perform all of them at once in a multiplexed molecular assay (8). Since recessive mutations are clinically significant only in the setting of reproduction, it follows that, whatever the approach, the ultimate goal of carrier testing and screening is to identify couples at risk so they can be offered the opportunity for prenatal testing.

### 23.2.5 Presymptomatic/Predisposition Testing

Predictive genetic testing is, in some ways, the most problematic of molecular genetic applications. It is

applied primarily to adult- or late childhood-onset autosomal dominant disorders. It is never appropriate as a screening test but is strictly reserved for individuals with a strong, usually parental, family history of the disorder, conferring on them a 50% a priori risk of having inherited the mutant gene. Depending on the penetrance of the mutations being tested, predictive testing is further subdivided into presymptomatic testing and predisposition testing. The former is applied to those disorders with virtually complete penetrance, such as Huntington disease, in which a positive DNA test result is fully predictive of eventual symptomatology (although not absolutely indicative of severity or age of onset). The latter is applied to diseases with reduced penetrance, such as familial breast/ovarian cancer due to mutations in the *BRCA1* and *BRCA2* genes, in which a positive test result confers increased risk of eventual disease compared to the baseline population risk, but does not allow prediction that any particular patient will actually experience the disease. This situation makes genetic counseling and clinical decision making much more difficult, especially for diseases like familial breast/ovarian cancer, in which risky or irreversible medical or surgical interventions may be initiated based on a positive DNA test result. With both types of predictive testing, there are significant psychosocial risks since otherwise healthy adults are being given potentially devastating news about future disease. There are also theoretical risks of insurance or employment discrimination (supposedly barred by the Genetic Information Nondiscrimination Act in the United States and similar laws in other countries) that beg the question of whether a nucleotide change predictive of future disease in a presently healthy person is to be considered a “preexisting condition.” For all these reasons, predictive genetic testing has been the area most scrutinized regarding standards for informed consent, pre- and posttest genetic counseling, and psychosocial supportive services. Because the offspring of patients with autosomal dominant disorders are aware of their risk, many such requests for testing are self-referred, and some of these individuals prefer not to involve their primary care provider or insurance carrier in the testing process. These special situations may place additional demands on genetic counseling services and on the testing laboratory.

## 23.3 TECHNICAL APPROACHES TO MOLECULAR GENETIC TESTING

### 23.3.1 Specimen Collection

Just as many of the applications are unique, so too the types of patient samples collected for molecular genetic testing may be different from those obtained for other types of clinical laboratory testing. Since germline mutations are present in every cell of the body, site-specific biopsy is not required and simple phlebotomy will suffice for most purposes (this is in contrast to the approach

for laboratory diagnosis of infectious and neoplastic diseases, where a specific lesion must be sampled). Alternatively, the great sensitivity of PCR allows for genetic testing to be performed on minute samples of any readily accessible tissue or body fluid, including saliva and urine. Newborn DNA screening can easily be performed on the same blood spots collected for biochemically based screening. For prenatal diagnosis, either amniocytes or CVS can be used, since both contain the full complement of fetal DNA. In addition, PCR-based single-cell genetic analysis now allows for preimplantation diagnosis on individual embryonic blastomeres, as discussed earlier, and most recently prenatal diagnosis targeting fetal DNA circulating in the maternal blood has become practicable (4), thus potentially obviating the need for any sort of invasive fetal sampling.

### 23.3.2 Selection of Technique

Once in hand, the specimen can be subjected to any of the molecular genetic techniques in the current armamentarium. The choice of technique will depend on the nature of the disease gene being studied (especially its size and mutational heterogeneity), the purpose of the test, and to some extent the condition of the specimen. Specimens that are extremely small, fixed, or degraded will require some sort of PCR-based analysis, since that technique is the most tolerant of suboptimal samples. Once amplified to an abundant amount, the DNA is then amenable to further analysis by other techniques such as allele-specific oligonucleotide (ASO) hybridization or DNA sequencing. Southern blotting, on the other hand, which is still used for certain tests involving large genomic DNA targets (such as the fragile X full mutation, although PCR-based methods have recently been developed (9)), requires intact DNA of high molecular weight in pristine enough condition to be digested efficiently with restriction endonucleases and to produce reproducible patterns on gel electrophoresis. This usually means at least a few milliliters of whole blood or one or two dishes of cultured amniocytes transported to the laboratory in a timely fashion. In either case, the first step is typically the isolation of DNA from the specimen, for which a variety of commonly used methods and commercial reagents are available.

**23.3.2.1 Detection of Known Point Mutations.** For detection of a known point mutation or microdeletion/insertion, the patient DNA sample can be hybridized with ASO probes that contain either the wild-type or mutant sequence within them. Since hybridization under high stringency can distinguish a single nucleotide change by mismatch of a probe with its target, using these ASO probes in pairs provides an internal control for accurately genotyping both heterozygotes and homozygotes. An alternative strategy capitalizes on the availability of a wide variety of bacterial restriction endonucleases with many different target recognition sequences. With

a little investigation (made easy these days through the use of computer DNA sequence analysis programs), it will often be found that the mutation of interest either disrupts a preexisting restriction enzyme cleavage site or creates a new one in the target DNA. In such cases, the mutation can be detected by exposing the patient's PCR-amplified DNA to the specific restriction enzyme and analyzing the cleavage products (sometimes called amplified restriction fragment polymorphisms, or AmpFLPs) by agarose gel electrophoresis. The same thing can sometimes be done by Southern blotting, since it too involves a restriction enzyme digestion step, although that approach is more laborious. PCR primers can also be designed to hybridize directly at the site of the mutation, in which case a mismatch between a wild-type primer and a mutant target sample will block amplification and produce a blank result. This technique has been called the amplification-refractory mutation detection system (ARMS).

The technical approaches just described are usually developed "in house" by the testing laboratory, often designated in the vernacular of the trade as "home brew" assays or "laboratory-developed tests (LDTs)." With the increase in test volume in molecular genetics in recent years, driven in large part by the advent of population carrier screening for CF and testing for common disease variants such as factor V Leiden, there has been a continuing movement by the laboratories toward more standardized, commercially prepared testing platforms. A few of these have gone through formal US Food and Drug Administration (FDA) review and can then be called "kits." Those that have not are sold as components of an assay that the laboratory must complete from some of its own sources and are designated "analyte-specific reagents" (10). In either case, these systems have proven robust and reliable and have generally been accepted as a boon to the field. Examples currently available for detection of point mutations include paper strip arrays of ASO hybridization probes, microarrays composed of chips or beads or a combination of the two, real-time PCR systems incorporating ASO probes with differential melting curves, oligonucleotide ligation with ASO probes analyzed by capillary electrophoresis, the Invader assay using specific cleavage of ASO hybrids to produce signal amplification by fluorescent resonance energy transfer, and mass spectrometry (11).

**23.3.2.2 Detection of Large Deletions.** Large deletions, while sometimes detectable by these methods, are usually more easily seen by Southern blot hybridization (signaled by the absence of one or more expected hybridization bands). Alternatively, one can use differential PCR amplification, in which the failure of one or both of a pair of PCR primers to hybridize to the target DNA because of the deletion will result in absence of an expected PCR product. Many primer pairs can be multiplexed to scan for unknown deletions across a gene, as

is done for the diagnosis of Duchenne muscular dystrophy (DMD). The main pitfall of this technique is that there are many other technical reasons for PCR failure (of artifactual origin), and so appropriate internal PCR amplification controls must be included in the assay. A more refined method now in common use is multiplex ligation-dependent probe amplification (MLPA) (12).

**23.3.2.3 Detection of Trinucleotide Repeat Expansions.** To detect the trinucleotide repeat expansion mutations characteristic of fragile X syndrome, Huntington disease, and other neuromuscular disorders, accurate sizing becomes important. Indeed, this is the most visible area of molecular genetic testing that approaches quantitative assay criteria, as opposed to the more qualitative observational assays for point mutations and deletions. If the expansion size is of moderate length, as in Huntington disease and the SCAs, amplification and sizing of PCR products suffices. This is typically done by capillary electrophoresis or automated DNA analysis instruments. For larger expansions that are difficult or impossible to amplify, such as in fragile X syndrome, sizing by Southern blot analysis or newer long-PCR methods is usually required.

**23.3.2.4 Detection of Heterogeneous or Unknown Mutations.** What about those disorders in which a wide range of point mutations has been reported, often spanning a very large gene? Such mutationally heterogeneous disorders present special problems to the laboratory in attempting to assure detection of a majority of the mutations; detection of all potential mutations is virtually impossible, even by complete DNA sequencing of the gene (since mutations may lie in noncoding regions, far upstream enhancers, etc.). Sequencing does cast the widest net and is therefore considered the “gold standard,” but it is not easily adaptable to high-throughput screening tests. As a compromise, one can select a more limited test panel comprising a few of the more commonly

recurring mutations in the gene, recognizing at the outset that some fraction of carriers will go undetected. These then become amenable to any of the targeted approaches discussed previously. These multiplex assays may be constructed at various density levels, depending on the number of sequence variants targeted. At highest density (up to a million or more probes) is the microarray or “DNA chip.”

DNA sequencing, because of its effort and expense, is usually reserved for situations in which it is not clinically acceptable to overlook a pathologic mutation if one is present; an example would be predictive testing for *BRCA1/2* mutations of familial breast/ovarian cancer. In other cases, sequencing may be used for detection of even a limited number of mutations in a gene, provided they are localized to hot spots within one or a few exons. These days most laboratories use automated DNA sequencer instruments, usually built on capillary electrophoresis. To confirm heterozygous single-nucleotide substitutions, which can sometimes be difficult to discern on these instruments (Figure 23-1), sequencing in both directions (i.e. sequencing both strands of the double helix) is recommended.

Finally, there are the so-called mutation scanning techniques. These can be used as a first-pass screen of a gene or gene fragment for the presence of point mutations, without the effort and expense of meticulous gene sequencing. These techniques capitalize on the altered three-dimensional topology of a mutant DNA fragment compared to the corresponding wild-type fragment, an alteration that can be detected by differential migration on electrophoresis. Popular techniques include single-strand conformation polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), and denaturing high-performance liquid chromatography (dHPLC). However, because they are qualitative assays relying on poorly understood physicochemical

**FIGURE 23-1** Example of automated DNA sequence readout on a capillary electrophoresis instrument, showing a heterozygous G-to-A substitution at position 416 of the connexin-26 (*GJB2*) gene. Any interpretive difficulty in discerning the heterozygous nature of the superimposed peaks can be confirmed by reverse sequencing.

behaviors of DNA fragments, they are never 100% sensitive. Furthermore, any abnormality detected must then be confirmed by DNA sequencing of the fragment for precise mutation location, identification, and interpretation. A rather different and more predictable mutation scanning technique is the protein truncation test (PTT), in which a gene or exon is used as substrate for an *in vitro* transcription/translation assay and the polypeptide products are analyzed by acrylamide gel electrophoresis. Presence of a nonsense mutation (or a frameshift mutation leading to a stop codon downstream) will produce a shortened (truncated) polypeptide as compared to a wild-type control. Of course, this technique will not pick up missense mutations, so a substantial proportion of pathologic alterations in the gene under study will go undetected. For all these reasons, and because DNA sequencing has become so much more rapid and less expensive in recent years, mutation scanning techniques are not used as much as they once were.

#### 23.3.2.5 Detection of Unknown Disease Genes.

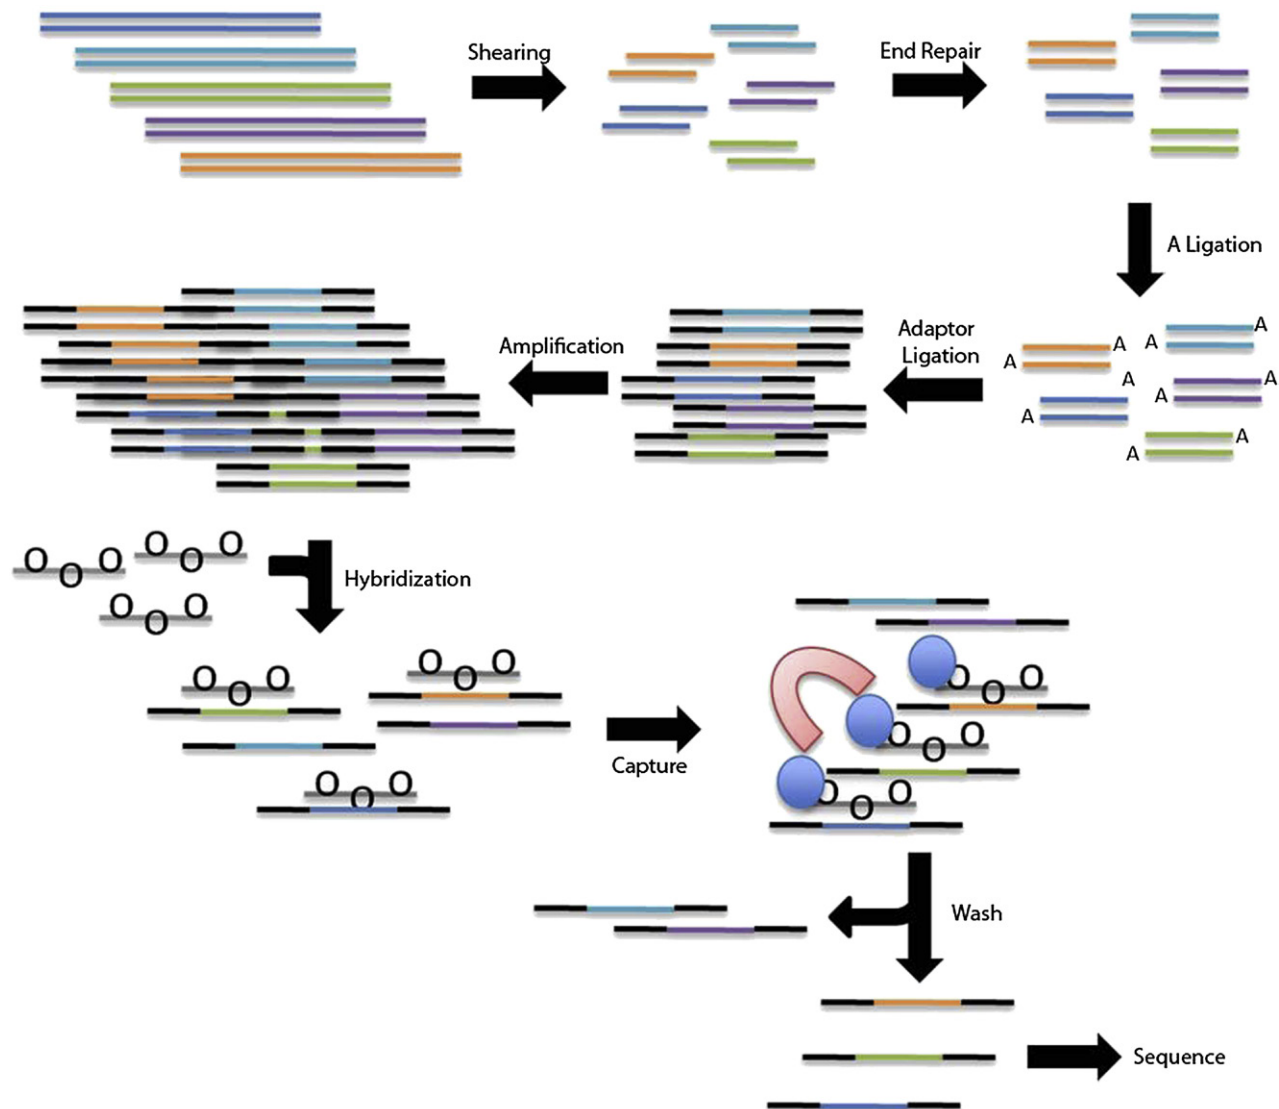

All the approaches listed earlier are direct mutation detection methods, which can only be used for disorders whose genes have been identified and cloned. Testing for diseases whose genes have not yet been identified but have at least been mapped to a particular chromosome requires linkage analysis, the use of polymorphic DNA markers to follow segregation of the mutant allele in a family group. This sort of testing requires collection of DNA specimens not only from the proband but also from multiple other affected and unaffected family members over two or three generations. Also required are polymorphic markers located sufficiently close to (or even inside) the disease gene so that false results due to crossing over are minimized. Although these are now available for most loci in the form of short tandem repeat markers, linkage analysis is not especially favored by diagnostic laboratories and instead is kept in reserve as a last resort for special situations involving diseases with unknown or very large genes. Linkage analysis is always more cumbersome and involved than direct mutation analysis; it has a higher risk of misleading results and requires family cooperation, which may not always be feasible. It is also typically more expensive, and reimbursement becomes awkward when third-party payers see multiple noncovered individuals being tested under the same billable procedure. Most laboratories are only too happy to leave it behind the instant the identification of the disease gene is reported.

Furthermore, the advent of massively parallel (next generation) DNA sequencing has placed linkage analysis even lower on the priority list, since it is now possible to accomplish both gene discovery and mutation identification by whole-exome sequencing of the proband and parents. Currently available next-generation sequencing platforms offer sequencing throughput

many orders of magnitude above that which is possible using traditional Sanger (dideoxy chain-termination) sequencing (13). The technology is based on the ability to perform many parallel DNA synthesis reactions in a manner that allows for the individual products to be analyzed. This parallelization is achieved through the addition of universal primers to DNA fragments that have been immobilized onto a solid support at a dilute concentration (Figure 23-2). Each DNA molecule is amplified, producing a colony of distinct fragments, and then the colonies are sequenced through the capture of images that reflect the base-by-base addition of nucleotides (Figure 23-3). Differences in sequencing chemistries of the various platforms result in differences in sequencing capacity, read length, and run time. When sequencing is complete, the resulting sequence reads are aligned against the consensus human genome sequence and all variants are listed, filtered, and annotated. It goes without saying that the computer informatics steps in this form of testing are just as important as the “wet bench” analytical steps.

**23.3.2.6 Interpretation of Novel Sequence Variants.** Because sequencing will detect any nucleotide change present—not just the previously known mutations in the gene—it becomes important to distinguish benign nucleotide sequence variants (polymorphisms) from pathologic ones. This is not as easy or straightforward as it may seem. While nonsense, frameshift, and splice-site mutations are usually quite obviously pathologic, especially if they occur prior to the 3′ terminus of the gene, missense mutations can bend the rules: even a mutation leading to an apparently conservative or synonymous amino acid substitution may somehow disrupt transcription or somatic stability down the line, and a major amino acid substitution may not be deleterious if it lies within a static or nonessential domain of the protein.

Given that roughly one in every thousand nucleotides in the genome is polymorphic and that we have not yet begun to scratch the surface in our sequence analysis of most genes, any laboratory performing whole-gene sequencing or whole-exome sequencing is going to have to deal with this conundrum. Both the College of American Pathologists (CAP) and American College of Medical Genetics (ACMG) guidelines stipulate that it is the laboratory’s responsibility to at least attempt an interpretation of the likely clinical significance of any novel variants discovered, rather than simply passing off the burden to the ordering physician. This interpretive discussion, even if admittedly somewhat speculative, must be part of the laboratory test report. Parameters that enter into this analysis include the nature of the amino acid substitution (conservative, nonconservative, and synonymous), the position of the substitution in the gene and protein product, phenotypic data on the variant if available in the medical literature or mutation databases, degree of evolutionary conservation of

**FIGURE 23-2** Schematic overview of next-generation sequencing methodology. Adapter ligation to short DNA fragments is followed by amplification, hybridization, and capture of select genomic regions prior to sequencing. The simultaneous capture of specific genomic regions is utilized when intending to test for only a panel of genes (e.g. for all the known genes associated with hypertrophic cardiomyopathy or hereditary hearing loss), as well as for sequencing all of the coding exons in the genome (also known as whole-exome sequencing). Whole-genome sequencing does not require any hybridization and capture steps to be performed. (Photo courtesy of Dr. Hane Lee, UCLA)

**FIGURE 23-3** Images from one of the commonly used next-generation sequencing platforms (Illumina). With this particular sequencing chemistry, the four nucleotides are each labeled with a different fluorescent dye. After addition of all four nucleotides to the chamber and excitation with a laser, a high-resolution image is captured to identify the newly incorporated nucleotide in a one-base extension step at all of the DNA fragment clusters. The reversible terminators are then removed, and a new cycle of sequencing is initiated. (Photo courtesy of Dr. Hane Lee, UCLA)

the nucleotide and amino acid in question, presence or absence of the variant in affected and unaffected relatives of the patient or in the general control population, in vitro functional studies (if available), and prediction of likely impact of the single nucleotide polymorphism

(SNP) on protein function using available programs such as PolyPhen and SIFT (14)—recognizing up front that none of these criteria or programs is absolutely predictive. ACMG has published guidelines for interpretation of sequence variants (15).

## 23.4 MOLECULAR GENETIC DIAGNOSIS OF PARTICULAR DISEASES

### 23.4.1 Cystic Fibrosis

It seems appropriate to begin the discussion of specific disease examples of molecular genetic testing with CF, since during the 1990s and 2000s it has come to be viewed as the prototypic challenge in DNA testing for mutationally heterogeneous disorders. Because it has one of the highest carrier frequencies of any serious autosomal recessive disease, it was considered a high-priority target for population screening ever since the causative gene was identified in 1989 (16,17). Because CF carriers have no detectable signs or symptoms to distinguish them from other members of the population, such screening could only be accomplished at the DNA level, making CF a “pure” molecular genetic disease from this standpoint. In addition, DNA testing for CF mutations allows for reliable prenatal diagnosis (provided the identity of both carrier mutations has been established in the parents) and for clinical diagnosis in cases in which the manifestations or the sweat chloride levels are atypical or borderline.

However, as is now widely known, the CF gene and in some sense the disease itself have proven resistant to simplistic approaches. While approximately 70% of Caucasian carriers have the common  $\Delta F508$  mutation, the other 30% (and an even greater proportion in other racial and ethnic groups) may have any of over 1800 other, much less common, mutations. The second most common mutation in non-Jewish Caucasians, G542X, has a frequency of only about 2%, and beyond the first six mutations, the individual carrier frequencies fall below 1% (18). Additional problems are raised by the extreme ethnic heterogeneity of the US target population, ethical issues surrounding prenatal testing for a disease of considerable clinical variability, the notoriously poor correlation between individual CF mutations and phenotypic expression (19), and a perception of inadequate genetic counseling resources to handle the caseload of nationwide screening (20).

As discussed earlier, the most assured way to pick up the greatest number of possible mutations in a large gene like *CFTR* (which spans 230kb and 27 exons (21)) is DNA sequencing. However, that procedure is too expensive for general population screening, and too comprehensive as well, in that missense variants of unknown significance will be found in an appreciable proportion of individuals. Screening requires a more targeted procedure such as allele-specific PCR or microarray hybridization with ASO probes. But which probes to use? Choosing a consensus panel of prevalent CF mutations was not a straightforward task, since all but one are rare, and the prevalence of individual mutations varies greatly according to ethnic group. Over the years, laboratories have employed panels of 6, 16, 30, or over 100 mutations, with remarkable diversity in practice from laboratory to

laboratory (22). After much deliberation, a core, panethnic panel of 25 mutations (along with some associated polymorphisms) was recommended by a subcommittee of the ACMG in order to bring some uniformity to the field and to offer the most efficient strategy for screening in an ethnically diverse population like that of the United States (23). The criterion used for inclusion in the panel was greater than 0.1% carrier frequency in the affected population as gauged by a large survey of CF patients (24); in addition, some mutations especially prevalent in ethnic groups likely to be screened, such as the W1282X mutation in the Ashkenazi Jewish population and the 3120+1G→A mutation in African-Americans, were included. This core panel produces carrier detectability rates of about 97% in Ashkenazi Jews, 80% in non-Jewish Caucasians, 69% in African-Americans, 57% in Hispanic Americans, and an uncertain, although very low, percentage in Asian-Americans.

As in many programs that quickly expanded from a limited pilot cohort to large-scale application, the early years of CF carrier screening revealed a few surprises. One mutation in the core panel, 1078delT, was found to be more rare in the general population than initially thought and would not have reached the 0.1% threshold for inclusion. Another one, I148T, was discovered to be a benign polymorphism and an incidental finding in affected patients who invariably had another, more rare, mutation in the same allele. Both of these variants have been removed in a revision of the panel announced in 2004 (25). Conversely, laboratories offering screening with larger panels discovered a number of other mutations with frequencies above the 0.1% threshold, but for reasons of uniformity and parsimony it was decided that these would not be added to the core panel for the time being. Also surprising was the relatively low uptake initially by obstetricians, despite the fact that offering this screening test to all pregnant couples (and those planning a pregnancy) was determined to be the standard of care. However, this situation has improved steadily over the years. Another, perhaps predictable, trend has been the tendency among some laboratories, especially on the commercial side, to offer ever larger mutation screening panels, even though the official guidelines discouraged the use of so-called extended panels beyond the core 25 (now 23), and it remains debatable how much added benefit such panels provide, especially at the cost of including some variants of dubious or poorly characterized clinical significance (7,26,27).

Laboratories and manufacturers have developed a variety of platforms to encompass whatever mutation panel is chosen. Some CF mutations can be differentiated by electrophoretic sizing and/or restriction endonuclease digestion of PCR products encompassing the codon in question, although this approach becomes somewhat laborious when targeting more than a handful of mutations. Reagent and equipment manufacturers have come forward with platforms to handle the much

**FIGURE 23-4** Results of oligonucleotide ligation assay (Abbott) on a specimen heterozygous for the *CFTR*  $\Delta$ F508 mutation. Following PCR amplification, allele-specific wild-type and mutant probes are hybridized to the corresponding DNA templates. Ligation to fluorescently labeled common probes followed by separation and detection by capillary electrophoresis allows for the simultaneous discrimination of a core panel of *CFTR* mutations.

higher sample throughput in CF carrier screening, in the form of ASO probe hybridization on paper strips, microarrays, bead arrays, oligonucleotide ligation assay (Figure 23-4), and single nucleotide variant analysis on automated DNA sequencers. A few laboratories now offer complete *CFTR* gene sequencing (28) and/or mutation scanning (29), but these approaches are more applicable to diagnostic testing than to carrier screening. They can also be helpful in identifying rare parental mutations in an affected child, which can then serve as targets for prenatal diagnosis in a subsequent pregnancy.

Another lesson from the CF gene story, since repeated in other diseases as well, is the broadening of the clinical phenotype as novel mutations are detected in increasing numbers and varieties of patients. It was already known that some CF patients may have minimal lung disease (30) or normal sweat chloride levels (31), but it later became apparent that there were individuals with mutations in the *CFTR* gene presenting with phenotypes not resembling classical CF at all. The gene has been implicated in such conditions as pancreatitis (32) and sinusitis (33), but most important has been the association of certain *CFTR* mutation and polymorphism combinations with an isolated congenital malformation, bilateral absence of the vas deferens (34). Especially associated with this condition are the R117H mutation and an intronic polymorphic tandem repeat of either five thymidines in *trans* or seven thymidines in *cis* (35); five thymidines in *trans* with other mutations can also produce the same malformation (36). The variable expressivity of the R117H mutation, requiring reflex testing for the poly T tract, has proved to be one of the more problematic aspects of the CF carrier screening program (37). However, CF is certainly not unique in this regard, and that is why the lessons we learn from the widespread molecular testing in this disease will be so relevant to many other applications in diagnostic molecular genetics.

### 23.4.2 Factor V Leiden and the Hereditary Thrombophilias

Similar to the CF carrier state, the Leiden mutation in the clotting factor V gene is a common enough allele (up to 7% in Caucasians (38)) that its DNA assay has been

considered as a screening test, if not in the general population then perhaps at least in those individuals already at risk for thrombosis due to environmental factors (surgery, paralysis, trauma, malignancy, and oral contraceptive use). Indeed, the DNA test itself is very easy, since the Leiden mutation (R506Q) disrupts an *MnlI* restriction endonuclease site present in the wild-type gene (39). There are also a variety of automated methods, microarray hybridization, and real-time PCR coupled with melt-curve analysis (14). Yet, also analogous to *CFTR*, the biology of this gene in vivo and in large populations is somewhat more complex.

The R506Q substitution renders factor V resistant to cleavage by activated protein C (APC), a key mechanism for keeping the coagulation cascade in check. It is the major (but not the only) cause of thrombophilia due to APC resistance. It is best to think of factor V Leiden as a genotype and APC resistance as the phenotype. As such, the latter can be diagnosed by functional coagulation assays on patient plasma, and some authorities believe that the functional assay is preferable to the DNA test as an initial diagnostic screen since it casts a wider net. On the other hand, technical modifications of the functional assay have made it almost entirely specific for the factor V Leiden etiology (40). In any event, the DNA test is certainly useful because of its lack of interference by anticoagulant therapy and its ability to reliably distinguish homozygotes from heterozygotes (Figure 23-5). The latter is important because heterozygotes have a 7- to 10-fold increased risk of venous thrombosis, while homozygotes have about an 80-fold increased risk (41). While these relative risk estimates may seem high, it is important to remember that idiopathic thrombosis in otherwise healthy adults, especially young adults, is quite rare; so the absolute risk, especially in heterozygotes, is not particularly great. In fact, the lifetime risk of an adverse event in a carrier is much less than the risk of complications from long-term anticoagulant therapy, which is the intervention presumably being considered in those testing positive. A similar risk differential can be stated for female carriers taking oral contraceptives who, as a result of DNA testing, might be obligated to seek other, less effective methods of birth control, leading to the risk of adverse events in unintended pregnancies

**FIGURE 23-5** Detection of factor V Leiden mutation by real-time PCR and melt curves with allele-specific probes (Roche Molecular Diagnostics). Each colored curve represents the genotype of a particular patient tested, illustrating a selection of wild-type (right peak), homozygous factor V Leiden (left peak), and heterozygous (both peaks).

(73)—although this notion remains somewhat controversial and varies depending on the hormonal makeup of contemporary birth control pills. In view of these low-magnitude relative probabilities, it is understandable that the concept of population screening of asymptomatic individuals for the factor V Leiden mutation has not been endorsed by either of two consensus statements issued by the ACMG (42) and CAP (43). The test remains useful, however, in differential diagnosis of otherwise unexplained thromboembolic events in patients under age 50 and in recurrent pregnancy losses. Because its main application is thus diagnosis rather than prediction, factor V Leiden analysis differs from many of the other genetic tests mentioned in this chapter. It is ordered primarily by internists, hematologists, and obstetricians rather than by geneticists and is widely viewed, rightly or wrongly, as a routine blood test rather than a genetic test. The consensus statements recognized this and did not require any pretest informed consent or genetic counseling (42).

Factor V Leiden is but one of a group of disorders classified as hereditary thrombophilias. While some of the others, such as protein S, protein C, and antithrombin III deficiencies, as well as variants in the factor VIII, fibrinogen, thrombomodulin, and platelet glycoprotein genes, are too rare and mutationally heterogeneous to become candidates for testing at the molecular level (44), there is one that approaches factor V Leiden in its indications and ease of testing. The prothrombin 20210A mutation (located in the 3'-untranslated region of the gene) leads to increased levels of prothrombin in the circulation and a phenotype similar to that of factor V Leiden (45). It too can be detected by restriction enzyme digestion of PCR products or by automated methods, including multiplex analysis with the factor V Leiden test (46,150). In addition, since it is also relatively common (1–2% carrier frequency), it makes some sense to test for it at the same time as factor V Leiden, provided the same indications are present. Some laboratories also include

in their thrombophilia DNA panel the 677C→T variant of the methylenetetrahydrofolate reductase (*MTHFR*) gene, which leads to elevated plasma homocysteine levels through inhibition of the folate-mediated remethylation of that compound. This allele is very common, found in 30–40% of the general population (47,152). Another variant, 1298A→C, has also been associated with elevated homocysteine levels when in compound heterozygosity with 677C→T. However, the phenotype is different from that for factor V Leiden and prothrombin 20210A, since elevated homocysteine is also associated with arterial (including coronary) thrombosis. Moreover, not everyone with an *MTHFR* variant exhibits elevated homocysteine, and not all cases of elevated homocysteine are caused by *MTHFR* variants. Furthermore, recent studies have called into question the fundamental association of modestly elevated homocysteine levels with thrombotic risk (48), and such elevation, even if present, is readily lowered by folate ingestion, either as a vitamin supplement or via widespread fortification in foods. For purposes of clinical decision making, therefore, there does not seem to be a compelling reason to lump this test in with the other two. On the other hand, since all three of these carrier states are quite common, it is not unusual to see double (or even triple) mutants, with documented synergistic effects on thrombotic risk (47,49). It should also be kept in mind that the prothrombin 20210A mutation has itself been implicated in myocardial infarction in women (50).

The anticoagulant system is extremely complex, and no doubt there are other hereditary factors yet to be discovered. Even though factor V Leiden is a single, simple mutant allele, the thrombophilic state behaves more like a complex, multifactorial disease, with numerous gene products interacting with one another and with environmental stresses. Sometime in the future, we might anticipate the advent of a “thrombophilia DNA chip” for screening, but at present one would be hard pressed to determine which of the many mutations and

polymorphisms that have been reported in hemostasis genes should be placed on such an array. For such a technology to be truly useful, we will need to achieve a much more thorough understanding of the biology of this complex system.

### 23.4.3 Hereditary Hemochromatosis

Despite the greater attention paid to CF, hemochromatosis is actually the most common inherited single gene disorder in people of northwest European ancestry. It is an autosomal recessive disease estimated to affect about 1 in 300 individuals in this population (51,153). The gene, *HFE*, is located 4.5 megabases telomeric to the HLA-A locus and encodes a major histocompatibility complex class I-like protein that regulates iron absorption from the intestine.

Two missense mutations, C282Y and H63D, have been identified within the gene (52). About 70–100% of hereditary hemochromatosis cases in various studies are homozygous for the C282Y mutation, which is carried by about 10% of Caucasian individuals (53). The other mutation, H63D, is found in a compound heterozygous form with C282Y in 3–5% of patients. These two mutations are in linkage disequilibrium and have not been found together on the same haplotype. However, considering the high carrier frequency of the H63D mutation in the general population (about 25%), its involvement in the pathogenesis of the disease remains controversial; it might represent a minor mutation of low penetrance or even a polymorphism (54). One recent large study of over 3500 affected patients found homozygosity for C282Y in 81%, homozygosity for H63D in about 1%, compound heterozygosity for C282Y and H63D in 6.7%, and combinations with another variant, S65C, in fewer than 0.5% (55).

Most laboratories offering *HFE* mutation testing assay for both mutations, while a few also include S65C. Molecular diagnostic testing for these mutations can be used to confirm the diagnosis of hemochromatosis in individuals with symptomatic disease, and potentially to detect those with presymptomatic iron overload in whom future disease manifestations may then be prevented by simple measures (regular phlebotomy). Because of the high carrier frequency, easy therapeutic intervention, and irreversibility of organ damage if not diagnosed early, hereditary hemochromatosis has been considered as a target for population screening. It remains controversial, however, because of the reduced and variable penetrance, even in C282Y homozygotes (56). While the penetrance of this genotype has commonly been quoted as about 70% (57), more recent surveys have suggested that it may be much lower, possibly less than 10% (58,59). It is also not clear whether, analogous to the situation with factor V Leiden, the functional assay (in this case, transferrin saturation and serum ferritin levels) might be the more appropriate initial screening test. In

a large survey of 100,000 individuals, assessed for both serum iron measurements and *HFE* genotype, biochemical differences between C282Y homozygotes and controls were variable, and no consistent deleterious effects of iron overload between the two groups could be demonstrated (60). It should also be noted that there are less common types of hereditary hemochromatosis caused by mutations in other genes such as *hepcidin*, *hemojuvelin*, and *ferroportin* (61).

### 23.4.4 Hereditary Hemoglobinopathies

Hereditary hemoglobinopathies encompass a vastly heterogeneous group of genetic disorders affecting globin protein structure and/or synthesis. Therefore, while the globin genes are relatively small compared to those of other important medical genetic disorders, the approach to their molecular testing is quite varied.

**23.4.4.1 Structural Globin Disorders.** While the greatest incidence of sickle cell disease occurs in sub-Saharan Africa, the carrier frequency in the African-American population is 8%, making it potentially a significant target for DNA testing and screening, although socioeconomic factors have impeded such efforts in the past. This is ironic considering that sickle cell disease was the first human genetic disorder for which the molecular basis was described. Later, the  $\beta$ -globin gene was the first human gene to be cloned and its various mutations demonstrated. Over 400 point mutations in the  $\beta$ -globin gene have now been identified, with the sickle cell mutation being the most common and most severe. While many of these can be identified by nonmolecular methods as well, it is important to remember that the number of structural variants that can be identified by standard hemoglobin (Hb) electrophoresis represents a minority of the total number in existence, because only approximately one-third of them produce an altered charge in the Hb molecule. In addition, in hyper-unstable Hb syndromes, the protein may be so labile or short-lived that electrophoretic identification is hampered. In these cases, DNA analysis will be preferable. For the same reasons, molecular testing can serve as a useful second-tier backup to newborn sickle cell disease screening by biochemical methods, even using the same blood spots (51).

The original DNA-based method for prenatal diagnosis of sickle cell disease used linkage analysis. An *HpaI* restriction fragment length polymorphism (RFLP) downstream of the  $\beta$ -globin gene was linked to the sickle cell mutation in 87% of African-American Hb S genes (62). Now, of course, direct mutation detection strategies are preferred. This can be accomplished by hybridizing labeled ASO probes complementary to either the  $\beta^A$  or  $\beta^S$  allele to genomic DNA blotted or spotted onto a membrane or array (63). Alternatively, one can use a PCR approach that capitalizes on disruption of a restriction endonuclease cleavage site by the HbS mutation. The mutation ablates an *MstII* or *DdeI* restriction site in

the gene, producing a larger fragment after enzyme digestion, as compared to normal DNA (64) (Figure 23-6).

Other structurally abnormal Hb disorders that may be detected in this manner include HbE, HbD-Los Angeles, and several rarer variants (65). The alternate mutation in codon six of  $\beta$ -globin causing HbC disease does not affect a restriction endonuclease recognition site and therefore must be detected with ASO probes (66) or ARMS. Multiplexing of ARMS primers to detect several globin mutations at once has been developed (67), as has competitive priming of fluorescently labeled primers (68).

**23.4.4.2 Disorders of Globin Synthesis—The Thalassemias.** Widespread population-specific screening of carriers for autosomal recessive disorders was initiated first with the thalassemias. Successful thalassemia screening programs have resulted in a marked reduction in the birth rate of affected children in Greece, Cyprus, continental Italy, Sardinia, Taiwan, China (Guangzhou), and South-east Asia (69). The thalassemias are a large and heterogeneous group of disorders of imbalanced Hb synthesis with widely varied phenotypic expression. From the laboratory perspective, the most important ones are  $\alpha$ - and  $\beta$ -thalassemia (and their respective intermediate subtypes).

**23.4.4.2.1  $\alpha$ -Thalassemia.**  $\alpha$ -Thalassemia is most commonly due to a deletion of one or more of the four  $\alpha$ -globin genes ( $\alpha_1\alpha_2/\alpha_1\alpha_2$ ). Deficits relate closely to gene dosage effects, and therefore dosage, and sometimes phase analysis, is an important component of the molecular diagnostic effort. Deletion of one  $\alpha$ -globin gene, usually the  $\alpha_2$ , is most common. These occur predominantly in two types, a 3.7kb deletion ( $-\alpha^{3.7}$ ) and a 4.2 kb deletion ( $-\alpha^{4.2}$ ). The  $-\alpha^{3.7}$  deletion is seen in individuals from Africa, the Mediterranean, the Middle East, and Oceania. The  $-\alpha^{4.2}$  deletion is seen in individuals from South-east Asia and the Pacific Islands (70). A subset of patients in certain ethnic groups may have point mutations in the  $\alpha$ -globin genes.

Since most  $\alpha$ -thalassemias are thus due to sizable deletions, Southern blotting of endonuclease-digested genomic DNA was traditionally used for

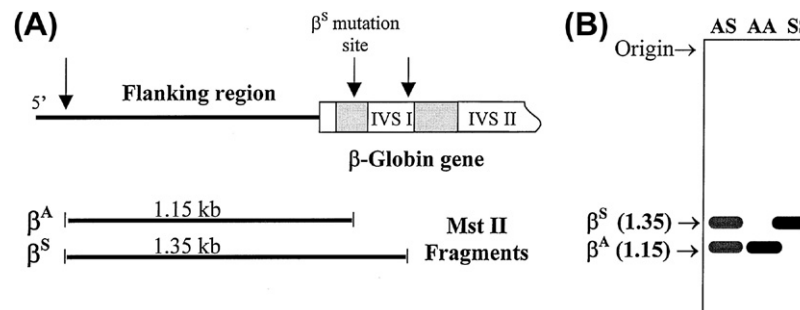

diagnosis, although now more modern techniques such as dHPLC and MLPA are usually used (12). The two  $\alpha$ -globin genes have divergence in their sequences in the 110-nucleotide-long 3'-untranslated region, allowing the presence of one or the other or both to be distinguished.

**23.4.4.2.2  $\beta$ -Thalassemia.** More than 200 different defects in the  $\beta$ -globin gene that result in  $\beta$ -thalassemia have been described. Molecular diagnosis of the  $\beta$ -thalassemias is made complicated by this heterogeneity. However, a unique spectrum of mutations is usually prevalent in a given population at risk for  $\beta$ -thalassemia. Fewer than 10 mutations usually encompass the majority of molecular lesions in the target population, making screening and prenatal diagnosis manageable (71). In fact, approximately 20 total mutations account for 80% of all the  $\beta$ -thalassemia alleles in the world.

Most  $\beta$ -globin gene defects (about 95%) that result in  $\beta$ -thalassemia syndromes are due to point mutations, including small deletions (up to 17bp) and insertions. About half these mutations completely inactivate the  $\beta$ -globin gene ( $\beta^0$ -thalassemia). This portion is caused by mutations in the initiation codon or the splice junction by or nonsense or frameshift mutations. The  $\beta^+$ -thalassemia mutations mainly affect transcription or messenger RNA (mRNA) processing, usually resulting from mutations located in the promoter region. Gross deletion (>24 bp) of the  $\beta$ -globin gene alone is quite rare, with fewer than 20 types seen (72). The deletion more often involves large segments of the  $\beta$ -globin gene cluster, resulting in  $\delta\beta^0$ - and  $\delta\beta^+$ -thalassemias. Depending on the number and variety of mutations expected, laboratories can choose any of a number of ASO or mutation scanning or sequencing strategies.

### 23.4.5 Trinucleotide Repeat Expansion Disorders

Trinucleotide repeats are members of the tandem repeat families found throughout the genome. However, unlike the more ubiquitous di- and tetranucleotide repeat

**FIGURE 23-6** Detection of the sickle cell disease missense mutation by restriction endonuclease digestion. (A) Schematic diagram of the 5' portion of the  $\beta$ -globin gene containing the sickle cell disease mutation site in codon 6. *Mst*II restriction endonuclease cleavage sites are indicated by the arrows. The abolition of one *Mst*II site by the  $\beta^S$  mutation results in an increase in size of the digest fragment from 1.15 to 1.35 kbp. (B) Schematic diagram of an electrophoretic gel or Southern blot in which the two fragments have been separated: AS, heterozygote HbS carrier; AA, normal control; and SS, HbS homozygote. (From Chang, J. C.; Kan, Y. W. A sensitive new prenatal test for sickle-cell anemia. *N. Engl. J. Med.* **1982**, 307, 30–32.)

polymorphisms, expansion of these triplet repeats to larger size can have a pathologic effect. Such expansion has been identified as a novel mutation mechanism in at least 15 neuromuscular disorders that result from instability of the expanded repeat once it has reached a certain length. The expansions are unstable mutations that tend to increase in size through successive generations, in contrast to repeat lengths in the normal range that are usually transmitted stably despite their polymorphic nature. The subsequent expansion of the repeat in descending generations does not adhere strictly to the rules of Mendelian inheritance because of the dynamic nature of the mutation and its variable expressivity. Anticipation is the hallmark of the trinucleotide repeat disorders, where increasing severity and earlier onset occur in successive generations and are correlated directly with the length of the repeat for some of the disorders. Parent-of-origin effect is also a feature.

Despite their shared features, trinucleotide repeat disorders can be separated into two distinct groups, type I and type II (74). Type I is composed of neurodegenerative disorders that are associated with neuronal loss in the brain, brainstem, and spinal cord. The members of this group are Huntington disease (HD), spinobulbar muscular atrophy (SBMA), dentatorubral-pallidoluysian atrophy (DRPLA), and the SCAs, SCA1, SCA2, SCA3 (Machado-Joseph disease), SCA6, SCA7, SCA8, SCA12 and SCA17. Type I disorders are all autosomal dominant, except for SBMA, which is X-linked. These diseases are caused by CAG (or CTG in SCA8) repeat expansions in the coding regions of the genes, resulting in the insertion of abnormally long polyglutamine tracts in the mutant protein. This change in the protein leads to a gain-of-function defect that is ultimately damaging to neurons in which it is expressed. The magnitude of

the intergenerational expansion is usually greater in male than female transmissions; the most severely affected individuals inherit the disease gene from their father. The type II disorders, in contrast, show a variety of clinical features other than neurodegeneration and involve repeat sequences other than CAG that are not in the coding regions of the genes. The sequence and expansion ranges of the repeats in the major trinucleotide disorders are summarized in Table 23-1.

#### 23.4.5.1 Type I Disorders.

**23.4.5.1.1 Spinobulbar Muscular Atrophy.** SBMA, known also as Kennedy disease, is a motor neuron disorder characterized by progressive muscle weakness and atrophy in males. The disease results from an expanded CAG repeat in the androgen receptor gene located at Xq12. The number of CAG repeats ranges from 9 to 34 in normal alleles. Affected males and carrier females have an allele with greater than 35 CAG repeats, detectable by PCR.

**23.4.5.1.2 Huntington Disease.** The unstable CAG repeat in HD patients lies in exon 1 of the *HTT* gene on chromosome 4p16.3. The CAG repeat length at this locus in the normal population ranges from 10 to 35, whereas in HD patients it ranges from 36 to 121, with a reduced penetrance at repeat sizes of 36–39. Strong inverse correlations between repeat length and age of onset have been observed. Adult-onset patients usually have an expansion in the range of 40–55, whereas juvenile-onset patients have expansions greater than 60 that are often inherited from the father. Sizing of repeat lengths is readily accomplished by PCR amplification and electrophoresis, best done on a capillary instrument for greatest accuracy (Figure 23-7).

Earlier PCR primer sets encompassed a neighboring nonpathologic CAG repeat, itself polymorphic, which

**TABLE 23-1 Mutation Ranges for the Trinucleotide Repeat Disorders**

Disease	Repeat Unit	Normal Range	Premutation or Partial Penetrance Range <sup>a</sup>	Affected Range
SBMA	CAG	9–34	—	36–62
HD	CAG	10–35	36–39	40–121
DRPLA	CAG	6–35	—	49–88
SCA1	CAG	6–34	—	39–81
SCA2	CAG	14–31	32–35	36–64
SCA3	CAG	12–37	—	64–84
SCA6	CAG	4–18	—	21–33
SCA7	CAG	4–35	28–35	37–200+
SCA8	CTG	16–92	—	110–130
SCA12	CAG	7–28	—	65–78
SCA17	CAG	25–42	—	45–63
Fragile X	CGG	5–54	55–230	230–1000+
DM	CTG	5–37	38–49	50–3000+
Friedreich ataxia	GAA	6–34	—	67–1700

<sup>a</sup>Absence of a listing in this column does not necessarily mean that the disorder has no premutation range, only that it has not yet been documented or well defined.

**FIGURE 23-7** Positive test result for HD trinucleotide repeat expansion. Fluorescently labeled primers (green) are used to amplify the HD CAG repeat region by PCR, and the fragments are separated and sized using capillary electrophoresis. One normal allele (<27 repeats) and one full mutation allele (>40 repeats) are evident on the above example. A second set of fluorescently labeled primers that encompass a neighboring polymorphic short-tandem repeat (blue) are run simultaneously in order to confirm the successful amplification of both alleles in cases when only a single peak is seen with the original set of green primers.

led to inaccurate sizing. Current PCR strategies do not include this repeat in the amplicon. However, the older primer set is still sometimes helpful for confirming two normal alleles when only a single peak is seen on the primary screen, which could indicate either homozygosity for a normal allele or failure to amplify a very large expansion. Southern blotting is another way to distinguish these two possibilities. Another reported reason for observing only a single band is PCR failure due to a “null allele” at the primer hybridization site on the opposite chromosome (75). Needless to say, accurate sizing of the repeat number in this disease is extremely important, not only because of the emotionally charged nature of the test but also since the difference in size between affected and intermediate or normal alleles is as little as three nucleotides.

HD was the first genetic disorder to be a target of presymptomatic molecular testing. Because of the virtually 100% penetrance of the full CAG expansion and the lack of any preventive therapy, a positive result in this test represents particularly devastating news, carrying risks of depression, suicide, and discrimination (76). For these reasons, standard practice for predictive testing emphasizes pre- and posttest psychosocial support and genetic counseling.

#### **23.4.5.1.3 Dentatorubral-Pallidoluysian Atrophy.**

DRPLA results in both ataxia and choreoathetosis, along with myoclonus, epilepsy, and dementia, so it is sometimes considered in the differential diagnosis of HD. The gene encodes a cytoplasmic protein with a polyglutamine tract in the middle. The number of CAG repeats in unaffected individuals ranges from 6 to 35, whereas in patients with DRPLA it ranges from 49 to 88. Molecular sizing is done as for HD.

#### **23.4.5.1.4 Spinocerebellar Ataxias.**

The SCAs are a group of genetically diverse neurologic conditions that

share progressive deterioration in balance and coordination due to degeneration of the cerebellum and its afferent and efferent pathways. Linkage studies identified multiple subtypes, eight of which have thus far been found to have unstable CAG (or CTG) expansions (types 1, 2, 3, 6, 7, 8, 12 and 17). The relatively small size of the SCA expansions (Table 23-1) allows for PCR-based testing as for HD.

**23.4.5.2 Type II Disorders.** The type II triplet repeat disorders include myotonic dystrophy (DM), fragile X syndrome, and Friedreich ataxia. In contrast to the type I group, these are multisystem disorders that are characterized by a constellation of symptoms involving many tissues. The repeat sequences are different in each, located in noncoding regions of the genes, and characterized by much larger expansions that may require Southern blot analysis for sizing. The expanding triplet repeats are located in the 5′-untranslated region of the *FMR1* gene in fragile X, in the 3′-untranslated region of the *DMPK* gene in DM, and, remarkably, in the first intron of the frataxin gene in Friedreich ataxia. The underlying molecular mechanism does not alter protein structure but rather alters the expression of the gene.

**23.4.5.2.1 Fragile X Syndrome.** Fragile X syndrome is caused by a large expansion of CGG repeats in the 5′-untranslated region of the fragile X mental retardation (*FMR1*) gene. The larger expansions are associated with increased methylation of both the repeat and the adjacent CpG island, leading to transcriptional silencing of the gene. The expansion and the subsequent methylation account for the presence of a fragile site (FRAXA) at chromosome Xq27.3 that results from a failure of normal chromatin condensation during mitosis.

Alleles of the CGG repeat can be classified as normal, premutation, or full mutation based on the number of the repeats. In the normal population, this repeat

**FIGURE 23-8** Southern blot analysis of the *FMR1* gene of fragile X syndrome. (A) *PstI* digestion and probing of genomic DNA: 1, normal control showing unexpanded allelic band at 1.0kbp and 2, patient with full CGG expansion mutation showing a spread of high-molecular-weight bands. (B) Southern blot methylation analysis by *EcoRI* and *EcoRI/BssHII* double digestion (*BssHII* is a methylation-sensitive restriction enzyme): 1, normal male showing single unexpanded, unmethylated allele; 2, affected male showing a single expanded and almost completely methylated allele; and 3, normal female showing two unexpanded alleles, one of which is methylated due to X-inactivation. (C) *PstI* digestion and probing of genomic DNA: 1, normal male; 2, female with one normal allele and one premutation allele; and 3, premutation male.

is highly polymorphic, ranging from 5 to 54 repeats, while in affected individuals the expansions range from about 200 to 230 to over 1000 repeats and are referred to as full mutations. The full mutation alleles are usually methylated and fail to express the *FMR1* mRNA and protein. Southern blot sizing of the *FMR1* expansion also includes use of a methylation-sensitive restriction enzyme to determine methylation status (Figure 23-8), which is especially important since some males with full but unmethylated expansion and no clinical symptoms have been reported (77). In addition, use of the methylation-sensitive enzyme allows separation of the two *FMR1* alleles in females, since the one located on the inactive X chromosome will be resistant to digestion because of intrinsic (nonpathologic) methylation. This approach helps to avoid overlooking a very large expansion in a female when only a single normal band is observed on the first-pass Southern blot (using a methylation-insensitive enzyme) or PCR. On the other hand, PCR is preferred for accurate sizing of premutations in carrier females, since the risk of expansion in offspring increases incrementally with increasing premutation lengths (78). Difficulty in amplifying the GC-rich premutation alleles of fragile X patients can be overcome by the addition of dimethylsulfoxide, 7-deaza-dGTP, and betaine to the PCR reaction, and recent innovations in primer design now allow for amplification and even methylation analysis of full mutations (9).

Large expansions display mitotic instability, resulting in a mixture of allele sizes within a single individual.

Premutation alleles ranging from about 55 to 200 are not typically associated with methylation, but they display instability in subsequent generations. These alleles may change in size when transmitted from either sex, invariably remaining within the premutation size range in male transmission but expanding to full mutation size in female transmission. (Alleles in the so-called “gray zone” of 45–54 repeats have a slight chance of expanding incrementally into the premutation range but not into the full mutation range.) The presence and location of AGG triplets interspersed within the CGG repeats in the *FMR1* gene also play an important role in the stability of the repeat. An uninterrupted pure CGG repeat of greater than about 33–39 triplets appears to increase the instability of maternal alleles (79,80). While it was long assumed that premutation carriers have a normal phenotype, we now know that they can cause late-onset effects, including premature ovarian failure in women and a middle-aged tremor-ataxia-dementia syndrome in men (81). Needless to say, the awareness of these phenomena now raises ethical concerns in the reporting of premutation results in fetuses and children, particularly if discovered as a consequence of population screening (5).

Identification of some families that were cytogenetically positive for the fragile site on chromosome Xq27-28 but negative for *FMR1* expansion led to the discovery of two more fragile sites, FRAXE and FRAXF, both located distal to FRAXA (82). Both involve GCC repeat expansion, with FRAXE exhibiting mild mental retardation in the absence of the characteristic physical stigmata

of FRAXA and FRAXF showing no apparent clinical phenotype. In practice, these two genes are not often investigated.

**23.4.5.2.2 Myotonic Dystrophy.** DM is the most common inherited muscle disorder in adults, with effects in many other organ systems as well. The genetic basis for DM is an expanded CTG repeat in the 3'-untranslated region of a protein kinase gene (*DMPK*). The size of the expanded repeat and the severity of the disease tend to increase in successive generations. The normal repeat size is 5–37 copies, while expansions range from 50 to more than 3000 in affected individuals. CTG repeat lengths in the range of 38–49 are considered “premutations.” In the range of 50–150 repeats, patients develop mild DM with cataract, mild myotonia, or diabetes mellitus, and they may have fully active lives and a normal or minimally shortened life span. In the range of 100–1500 repeats, patients usually develop classic DM with muscle weakness and wasting, myotonia, cataracts, and often cardiac conduction abnormalities, with the age of onset typically in the 20s and 30s. Most infants with congenital DM have more than 1000 CTG repeats, with mental retardation (in 50–60% of cases) and early death. Infants with congenital DM nearly always inherit the expanded *DMPK* allele from the mother, but inheritance from the father is possible. Because of the large size of some DM expansions, “long PCR” or Southern blotting may be required for diagnosis.

**23.4.5.2.3 Friedreich Ataxia.** Friedreich ataxia, the only autosomal recessive among the triplet repeat disorders, is caused in 97% of patients by the expansion of a GAA repeat in the first intron of the frataxin gene. The level of frataxin protein expression is decreased in affected individuals with expanded repeats, presumably by an inhibitory effect of the intronic repeat on transcription (83). The larger the repeat, the greater the effect on mRNA and protein levels. Normal individuals have 6–34 uninterrupted GAA repeats, and affected patients have 67–1700 repeats. Sizing can be accomplished by either PCR or Southern blotting (Figure 23-9). Compound heterozygotes have been identified in a small percentage of cases with a triplet expansion in one allele and either a nonsense mutation, missense point mutation, or initiation codon mutation in the other allele. This makes the results reporting rather complicated, since the methods used for repeat sizing will not pick up point mutations, and referral to a specialized laboratory offering full gene sequencing may be required.

**23.4.5.3 Duchenne and Becker Type Muscular Dystrophies.** Duchenne (DMD) and Becker (BMD) muscular dystrophies are allelic forms of an X-linked neuromuscular disorder that affects about 1 in 3500 live male births. Both are caused by mutations arising in the gene encoding dystrophin, a cytoskeletal protein that underlies the plasma membrane of normal skeletal muscle. The dystrophin gene is located on the short arm of the X chromosome (Xp21) and is one of the largest

**FIGURE 23-9** PCR analysis of Friedreich ataxia GAA trinucleotide repeat expansion. Arrow indicates the size of PCR products generated from normal alleles. The samples shown are 1, normal; 2, homozygous expanded; and 3, heterozygous.

genes ever characterized, spanning 2.4 Mbp and encoding 79 exons (84). The gene has an unusually high rate of intragenic recombination of about 10–12% in normal pedigrees (85). Recombination events appear to occur mostly in two hotspots located between exons 1–8 and exons 44–51 (86). The majority of the mutations are intragenic deletions (~65%) or duplications (5%) (87,88). The remaining one-third of cases are due to point mutations such as microdeletions, insertions, and substitutions. According to the frameshift hypothesis proposed by Monaco et al. (89), a patient most likely develops a DMD phenotype if the mutation disrupts the reading frame, whereas a BMD phenotype results if the reading frame is maintained. This would explain the apparent paradox of even fairly large BMD deletions producing a mild phenotype. At the protein level (e.g. on Western blot), DMD is seen to be caused by the absence of detectable dystrophin, whereas muscle from BMD patients shows a protein of reduced size at less than 40% of normal levels.

Since DMD is a serious disorder for which at present there is no effective treatment, much emphasis has been given to prevention. This involves the ascertainment of

women at risk of giving birth to affected sons and the provision of genetic counseling and prenatal diagnosis. Accurate carrier detection and genetic counseling depend on first identifying the mutation itself in the proband. The current strategy for DNA testing in this disorder was developed to attempt to circumvent problems arising from the unusual features of the gene, such as its very large size and the great variety of mutations. The approach will vary somewhat depending on the intent and indications for testing, as described in the following paragraphs.

**23.4.5.3.1 Detection of Large Deletions in Patients.** The original method for detecting large deletions was the Southern blot. This approach uses full-length or partial complementary DNA probes to detect deletions by the absence of hybridization or appearance of novel hybridizing bands (junction fragments) (90). This is a laborious method, which may take several weeks to complete if multiple probes have to be tested sequentially. It has now largely been supplanted by a PCR method that uses two sets of multiplex primers, each covering deletion hotspots in various exons of the dystrophin gene (46,91). Deleted exons fail to be amplified and are recognized as absent bands on the electrophoretic gel of the PCR products (Figure 23-10). Because the PCR method screens many regions of the gene simultaneously, it is dramatically faster than the Southern blot approach, with results possible in one day.

**23.4.5.3.2 Detection of Large Deletions in Carriers.** Once a deletion is identified in an affected patient, DNA samples from women at risk in the family can be tested for carrier status. The assay is complicated, however, by the presence of two X chromosomes, so the particular deletion must be detected by dosage analysis. The woman's DNA is subjected to Southern analysis using the same probe that detects the deletion in the related patients. If done carefully, a deletion in one of her two dystrophin alleles results in autoradiographic bands with half the normal intensity (92). Dosage analysis can also be performed by combining the multiplex PCR assay with capillary electrophoresis to measure the height and/or integrated area of each product peak. Alternatively, the deletion can be identified directly if a junction fragment is observed on the Southern blot autoradiogram (93). A junction fragment arises as the result of fusion of the two DNA fragments flanking the deletion, producing a hybridizing band of abnormal size. Unfortunately, however, junction fragments are found in less than 5% of patients tested. As it has for diagnosis, carrier detection has now moved into the PCR era, and a number of quantitative and multiplex approaches are available that can readily detect deletions and duplications, even in the carrier state, and cover all 79 exons of the gene (94,95).

**23.4.5.3.3 Detection of Microlesions in Patients and Carriers.** One-third of mutations in the dystrophin gene are base substitutions or microdeletions/insertions. Several methods have been used to screen the gene for these microlesions, including the

**FIGURE 23-10** Multiplex PCR for detection of dystrophin deletions in Duchenne/Becker type muscular dystrophy, by the method of Beggs et al. (149). The samples shown are C, normal control showing PCR products corresponding to (from top to bottom of electrophoretic gel) promoter and exons 3, 43, 50, 13, 6, 47, 60, and 52; 1, patient positive for a deletion involving exon 13; and 2, patient positive for a deletion involving exon 6.

mutation scanning techniques introduced earlier: SSCP, heteroduplex analysis, chemical mismatch cleavage, DGGE, and PTT (96,97). More recently, the advent of next-generation DNA sequencing has rendered the huge dystrophin gene amenable to complete sequencing and direct detection of point mutations (98). Once the mutation is found in a patient, reliable carrier detection is possible by sequencing only the region containing that particular mutation using the Sanger technique.

In families in which the mutation cannot be detected, carrier risk can be assessed by serum creatine kinase (CK) levels in female relatives and linkage analysis using flanking and intragenic markers. These markers can also support the identification of deletion mutations, exclusion of maternal cell contamination in CVS, confirmation of paternity, and mapping of dystrophin gene recombinations.

Female relatives of DMD and BMD patients often request genetic counseling, genetic testing, and prenatal diagnosis. As a first step, a pedigree analysis is helpful in evaluating the carrier status in a female. A woman with an affected son and affected relatives from her maternal side is an obligate carrier. A woman with one or more

affected brothers but no affected offspring is a possible carrier. A woman with more than one affected son and no family history of muscular dystrophy is a full carrier, a germline mosaic, or a somatic mosaic including her germline (99). Subsequent brothers and sisters of a patient with a “new” mutation have an estimated risk of 5–10% of inheriting the same germline mutation. Prenatal diagnosis is readily achieved by molecular detection of mutations using chorionic villi or amniocytes.

### 23.4.6 Prader–Willi and Angelman Syndromes

Despite their disparate clinical phenotypes and completely independent genes, these two disorders are forever linked in cytogenetics and molecular genetics laboratories because of their coincident deletion sites on chromosome 15q11–q13 and mirror-image imprinting mechanisms. About 70% of cases of both disorders are due to deletions at this locus, some of which are too small to be visible by chromosome banding, although they may be detected by fluorescence in situ hybridization. Most of the remainder are due to uniparental disomy (UPD) in Prader–Willi syndrome (PWS) and point mutations in Angelman syndrome (AS). About 10% of AS cases are due to an imprinting defect, while a smaller proportion (3–5%) are due to UPD. The small fraction of PWS cases not due to deletion or UPD apparently involve an imprinting defect. Owing to the imprinting phenomenon active at this locus, the AS gene (*UBE3A*) is expressed only on the maternally inherited chromosome 15, while the PWS gene (which is still not identified) is expressed only on the paternally inherited chromosome. Thus, loss of maternal *UBE3A* gene expression by either deletion or UPD for the paternal allele will produce AS, while loss of the paternal PWS gene by either deletion or UPD for the maternal allele will produce AS. As mentioned, loss of *UBE3A* function through point mutation is also seen in AS, but whether or not it occurs in PWS will not be known until the gene is identified. Either disorder can also be produced by aberrant parental gene expression due to a primary imprinting defect.

Molecular genetic testing for these disorders is aimed at tracking the maternal and paternal alleles and determining whether one or the other is either missing (deletion) or duplicated (UPD); obviously, the UPD mechanism results in both duplication of one allele and loss of the other. The two parental alleles can be distinguished from one another because of the differential methylation that occurs at this locus, using Southern blotting following digestion of patient DNA with a methylation-sensitive restriction enzyme (100), methylation-sensitive PCR, or real-time PCR (101). The PCR technique capitalizes on the property that exposure of DNA to sodium bisulfite converts cytosine to uracil except when it is methylated. Primer or restriction endonuclease digestion can be designed to distinguish this difference at a site within

**FIGURE 23-11** PCR-based methylation analysis of the Prader–Willi/Angelman region on chromosome 15, using the sodium bisulfite method. The upper band corresponds to the maternal allele and the lower band to the paternal allele. The samples shown are 1, normal; 2, AS; and 3, Prader–Willi syndrome.

the critical locus, such as the *SNRPN* gene. A missing maternal allele is diagnostic of AS, while a missing paternal allele indicates PWS (Figure 23-11). The real-time PCR technique relies on differential melting curves of methylated vs. nonmethylated CpG sequences. None of these approaches can distinguish between the deletion and UPD mechanisms, however, although in actual practice the difference is not critical since both have very low recurrence risks. Documentation of UPD requires microsatellite analysis of chromosome 15 in the patient and parents, demonstrating homozygosity for the polymorphic alleles, or observation of long stretches of homozygosity on chromosomal microarray analysis. PWS or AS caused by imprinting defects (presumably involving aberrant methylation) will also not be distinguished by these methods (although the tests will still be positive), which is unfortunate because those cases do have a much higher recurrence risk (102). This mechanism is usually established by exclusion of the other molecular defects and is otherwise difficult to prove. However, a microdeletion of the putative imprinting center can be demonstrated in some cases (103).

### 23.4.7 Familial Cancer Syndromes

The advent of counseling for and diagnosis of hereditary cancers represented something of a paradigm shift for the specialty of medical genetics, and one with which it has yet to come completely to terms. Indeed, it is safe to say that it would not even be part of the specialty, remaining instead within the exclusive domain of oncologists, were it not for the advent of molecular diagnostic testing with all its risks and complexities. After all, familial cancers have always been with us, but they have come to the forefront of public consciousness only in the last 15–20 years because there are now predisposition tests for some of the major malignancies. In most cases these are not simple tests with clear-cut results; extreme mutational heterogeneity and variable penetrance make their performance and interpretation quite difficult. These factors, and the theoretical risks of insurance discrimination and adverse psychosocial impact, have led to

practice guidelines mandating pre- and posttest genetic counseling for some of them. Indeed, there are documented cases of serious misinformation ensuing when these procedures are not followed (104).

There are at least 35 strongly heritable syndromes in which various cancers are a primary manifestation (105). This section considers only those autosomal dominant forms for which DNA testing has become prevalent. All of them have in common a pathogenetic mechanism fitting the classical tumor suppressor gene model.

**23.4.7.1 Familial Breast/Ovarian Cancer.** While it was the retinoblastoma gene many years before that first defined the “two hit” model of dominantly inherited cancer, it was the discovery of the *BRCA1* and *BRCA2* genes that really put familial cancer on the map for the medical genetics community and led to only the second routinely offered presymptomatic genetic test after HD. In fact, the two tests are often discussed as instructive analogies for one another, yet they could hardly be more different. Mutations in the HD gene show virtually 100% penetrance, giving the DNA test an extraordinarily high predictive value, while *BRCA1/2* mutations may only be 50–85% penetrant for breast cancer and 25–45% penetrant for ovarian cancer in various families (106). HD has no prevention or treatment (yet), while breast cancer (and to a lesser extent ovarian cancer) can be prevented in some cases by prophylactic surgery and/or medication and screened for early detection. Breast cancer is one of the most common serious diseases in medicine, affecting roughly 1 in 9 women, although it is important to keep in mind that the *BRCA1/2* genes account for only 10% of this incidence at best. Finally, and most important from the perspective of this chapter, HD shows only a single species of easily detectable mutation (the CAG triplet repeat expansion), while *BRCA1/2* mutations and variants are extremely heterogeneous and still not yet completely characterized.

Because of its difficulty and expense, the potential risk of stigmatization or other adverse psychosocial reactions, and the not uncommon finding of nucleotide changes of unknown significance within the gene imparting even more uncertainty to the patient than she had before the test, *BRCA* testing should never be undertaken lightly. Initially there was a general consensus that testing not be encouraged unless the a priori risk of the proband testing positive exceeds 10% (although this strict numerical cutoff has since been relaxed somewhat (107)), and there are several formulas for making this estimation based on personal and family history, ethnicity, and other factors (108,109). Of course, testing of minors should not be considered outside of exceptional circumstances, since there is a risk of misunderstanding and stigmatization for a condition that has no symptomatic onset or clinical intervention until adulthood.

The *BRCA1/2* genes are very large, and hundreds of mutations have been reported, spread diffusely across the length of both genes. In this sense they are similar,

from a molecular testing point of view, to the *CFTR* gene. However, while the clinical impact of missing a carrier of a rare *CFTR* mutation in a population screening program does not justify the cost of sequencing the gene, the adverse consequences of missing a *BRCA* mutation in a presymptomatic test are great enough that full sequencing of both genes is justified despite the cost (assuming there was a strong enough personal or family history to consider testing in the first place). Patients testing negative must be cautioned that even complete sequencing could potentially overlook a mutation in an unusual location (outside the coding region), and also that it is possible the cancer in their family was due to a non-*BRCA* etiology. One class of mutations known to be missed by DNA sequencing are large deletions. Since it is now recognized that these constitute a significant minority of *BRCA* mutations, screening for exon dosage by either Southern blotting or quantitative amplification has become an important component of the testing process (110).

There are two major exceptions to the need for complete gene sequencing in *BRCA* testing. One is the situation in which the mutation in the family is already known from prior testing of an index case (something that should always be sought if the affected relative is available). The other is in the Ashkenazi Jewish population, in which three recurring mutations account for the vast majority (at least 90%) of *BRCA* carriers: 185delAG and 5382insC in *BRCA1* and 6174delT in *BRCA2* (111). Individuals in this ethnic group can be offered a limited screening panel (Figure 23-12) at much reduced cost, although if they test negative in the absence of a known mutation in the index case, the difficult question of pursuing more comprehensive testing of lower yield will arise.

While clinical follow-up is continuing, initial outcomes data indicate dramatic, although not absolute, reduction in breast and ovarian cancer incidence in women testing positive for *BRCA* mutations presymptotically, who then opted for prophylactic surgery. Importantly, in premenopausal women, oophorectomy reduces not only the incidence of ovarian cancer but that of breast cancer as well (112,154).

**23.4.7.2 Hereditary Nonpolyposis Colon Cancer.** Colon cancer, like breast cancer, is a common disease, and similarly, about 10% of cases have a strong familial component. The dominant form of adult-onset colon cancer, as distinguished from familial adenomatous polyposis, is hereditary nonpolyposis colon cancer (HNPCC, also known as Lynch syndrome), characterized by predisposition to early-onset (average age 44 years) tumors mostly proximal to the splenic flexure. Some forms (Lynch II) are associated with other adenocarcinomas of the endometrium, ovary, small bowel, stomach, pancreas, and other organs. Ascertainment of HNPCC families based on history is done using the Amsterdam criteria or their subsequent modifications (113,114),

**FIGURE 23-12** Targeted detection of the Ashkenazi Jewish *BRCA1* founder mutation 185delAG by automated sequencing analysis. Because this is a heterozygous two-nucleotide deletion, it results in a heterozygous frameshift on the sequencing readout, causing mismatched nucleotides and overlapping peaks following the mutation site (arrow).

again recognizing, just as in hereditary breast/ovarian cancer, that overly strict adherence to such guidelines results in falsely excluding some affected families (115).

At least five genes are known to be responsible for HNPCC: *MSH2*, *MLH1*, *PMS1*, *PMS2*, and *MSH6*; the first two account for about 70% of the cases (116). The protein products of these genes are involved in DNA mismatch repair, producing the so-called replication error or mutator phenotype in tumor cells. The latter can be assayed in the molecular diagnostic laboratory by observing novel, nongermline bands in electrophoretic analysis of short tandem repeat loci (Figure 23-13), a phenomenon called microsatellite instability (MSI). Indeed, this is an easier test than searching for the many possible mutations in the five causative genes, although it is not entirely sensitive or specific for familial colon cancer (about 15% of sporadic colon cancers also exhibit the phenomenon). However, it may be helpful in estimating whether a colon tumor is due to HNPCC when the family history is incomplete or ambiguous (117). The presence of MSI also has some prognostic and management value, as these tumors tend to be more responsive to standard therapies (118). Direct mutation testing of the five dominant genes by the same approaches used for the *BRCA* genes is available, although expensive. It can be offered to patients and relatives meeting the family history criteria and to those whose tumors demonstrate MSI. Analysis usually starts first with *MSH2* and *MLH1* and then proceeds to the other genes if those are negative. As for *BRCA* testing, the possibility of large deletions invisible to standard sequencing, and missense variants of uncertain clinical significance, must be considered. In index cases from whom tumor tissue is available, analysis of the mismatch repair gene products by immunohistochemistry may offer a less expensive initial screen to allow selection of the particular impaired mismatch repair gene for sequencing.

**23.4.7.3 Familial Adenomatous Polyposis.** This autosomal dominant syndrome is characterized by early onset (childhood or young adulthood) of large numbers of colonic polyps with high malignant potential, along with benign and malignant lesions in a number of other tissues. It is due to mutations in the *APC* gene, which are quite numerous and heterogeneous, although the majority are of the nonsense or frameshift class. Individuals

**FIGURE 23-13** Polymorphic short tandem repeat analysis of paired blood and colonic tumor DNA samples, illustrating extra, nongermline alleles (arrows) in the tumor DNA indicative of MSI. (Red peaks are internal size markers.)

with the “attenuated” form of familial adenomatous polyposis (<100 polyps) tend to have mutations near the 5′ or 3′ ends of the gene (119). This is one of the few predictive genetic tests acceptable for performance in children, because of the early onset of polyps and the onerous clinical surveillance procedures.

**23.4.7.4 Multiple Endocrine Neoplasia.** Multiple endocrine neoplasia (MEN) type 1 is characterized predominantly by neoplasms in the parathyroid, pancreas, adrenals, and pituitary. MEN type 2 features medullary thyroid cancer, pheochromocytoma, and hyperparathyroidism. A subtype, MEN2B, is further characterized by marfanoid habitus, ganglioneuromas, and mucosal neuromas.

The gene for MEN2, the *RET* proto-oncogene, was discovered first, and DNA testing has proved quite valuable for at-risk family members. Indeed, the *RET* gene seems to be everything the *BRCA* genes are not: it contains a limited number of mutations localized to a few exons, and the penetrance is virtually 100%. In fact, most of the mutations in MEN2A are found in exons 10 and 11, with a single cystine codon (number 634) most commonly affected with every possible missense substitution of its three nucleotides. Less common mutations have also been found in exons 13 and 14 (120). Furthermore, almost all cases of MEN2B, which have a unique presentation, show a single missense mutation at codon 918 in exon 16. Thus, molecular genetic testing for MEN2 is very straightforward, typically involving ASO probes or limited sequencing of the mutable exons to identify almost all carriers. Because the penetrance is so high and the highly aggressive medullary thyroid cancers can occur in childhood, *RET* gene analysis is another predictive genetic test indicated for use in presymptomatic children.

The MEN1 gene (designated simply *MEN1*) was identified more recently and has been less subject to testing because of the large number of mutations (>400) described. Most of them are of the nonsense, frameshift, or deletion variety (121) and are typically detected by sequencing.

**23.4.7.5 Other Dominantly Inherited Cancer Syndromes.** Molecular tests are available on a more limited basis for the less prevalent familial cancers. Just a few of the more prominent examples will be mentioned here.

*Li–Fraumeni syndrome*, characterized by a wide variety of tumors in affected families (breast, brain, sarcoma, leukemia, lung, pancreas, etc.), is caused by germline mutations in the *p53* (also designated *TP53*) tumor suppressor gene. The mutations are diverse and must be distinguished from the somatic *p53* mutations that are found in many nongenetic tumors (122).

*Familial melanoma* accounts for about 10% of all melanomas and may be associated with the dysplastic nevus syndrome. Sequencing of the implicated *CDK4* and *CDKN2A* (also designated *p16*) genes is available (123).

*Von Hippel–Lindau disease* exhibits a variety of benign and malignant tumors, most prominently renal clear cell carcinoma. The causative *VHL* gene contains only three exons and so can be sequenced readily, but about a fourth of the mutations are large deletions that must be detected by another method, such as Southern blot or MLPA (124).

*Retinoblastoma*, the cancer that set the stage for our understanding of tumor suppressor gene action, remains one of the more difficult to test for, owing to the large size of the *RB1* gene, the complexity of the mutations, and the rarity of the disorder. However, sequencing and mutation scanning approaches are available in a few laboratories (125).

## 23.5 MITOCHONDRIAL DNA DISORDERS

Lastly, we must not forget about “the other human genome,” the one that exists outside the nucleus, in those energy-generating organelles called mitochondria. Notwithstanding the emphasis of the Human Genome Project on identifying disease-associated genes in the nuclear genome, the mitochondrial genome is subject to pathogenic mutations as well and thus is fair game for molecular diagnostic attention. In fact, the mutation or replication error rate of mitochondrial DNA is substantially higher than that of nuclear DNA, making the mitochondrial genome highly polymorphic between individuals and heteroplasmic within different cells and tissues of the same individual. This latter property in particular makes DNA-based diagnosis of mitochondrial disorders tricky and subtle. Because polymorphisms are usually homoplasmic and mutations are usually heteroplasmic, mitochondrial DNA diagnostic techniques must be of sufficient sensitivity to detect alterations in a portion, or even a minority, of cells (similar to infectious disease and oncology testing), yet of sufficient specificity and clinical predictive value to distinguish them from benign polymorphisms. Next-generation DNA sequencing, because of its ability to sample even minor subpopulations in parallel with the majority, without being diluted out, may be particularly amenable to this application (126).

The 16.5 kbp mitochondrial genome carries genes for 13 polypeptides (components of the respiratory chain), 22 transfer RNAs, and two ribosomal RNAs, and mutations may be found in any one of them (127). Since a number of these mutations are recurrent in particular disorders, a common approach is to test first for some of these as a panel, such as the G11778A mutation, which is found in 50–70% of patients with Leber’s hereditary optic atrophy, or the A3243G mutation, found in a large proportion of patients with myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). Laboratories may offer one or more core mutation panels to be employed as a first-tier test depending on the clinical presentation of the patient, to be followed by another panel or a wider mutation

scanning method if the first test is negative (128,129). The protocol requires close communication with the referring physician in order to decide which panel to utilize and just how far to pursue a mitochondrial etiology that may in fact never be found. In embarking on such testing, the phenomenon of heteroplasmy must always be at the top of one's mind, even from the point of specimen collection: mitochondrial DNA testing may require sampling of the affected tissue, rather than simple phlebotomy, in order to increase the chances of finding the causative mutation.

### 23.6 OTHER TARGETS OF MOLECULAR GENETIC SCREENING

As of 2012, GeneTests, the online directory of molecular genetic testing laboratories (<http://www.ncbi.nlm.nih.gov/sites/GeneTests/?db=GeneTests>), lists over 2500 different disorders for which DNA-based tests are available. Many of these disorders are quite rare, and 11% are offered only on a “research” basis by the investigating laboratories that are studying the genes in question. These are true “orphan” diseases, lacking the test demand to be of interest to mainstream clinical molecular genetics laboratories, and thus the research laboratories fulfill a vital service in making this testing available to families at risk. At the same time, it must be recognized that they are operating outside the legally accepted domain of clinical laboratory testing (at least in the United States), since most of them do not have certification or licensure under the Clinical Laboratory Improvement Amendments (CLIA) guidelines or by other regulatory bodies. Given that most research laboratories would not find it practical or desirable to pursue such certification, while the established clinical laboratories are not interested in assuming the burden of such low-volume and esoteric tests, the best solution seems to lie in the establishment of a network of orphan testing dedicated to covering the aggregate of these rare disorders (130).

At the other end of the spectrum are diseases resembling CF in that they have high carrier frequencies but for one reason or another they have not yet been taken up as targets for large-scale screening. One such example is **spinal muscular atrophy**, with a carrier frequency of about 1 in 50 for mutation in the *SMN1* gene. Given the severity of the disorder and a mutation carrier frequency that approaches that of CF, one might think it an obvious target for population screening. But molecular testing, especially for carriers, is quite challenging because of the presence of a closely homologous adjacent gene, *SMN2*, which can be present in multiple copies and can have a mitigating effect on the phenotype (131). Despite a recommendation from ACMG that population carrier screening be implemented (155), uptake has been slow, and there has been some pushback from the obstetric providers (132).

Another example is **congenital hearing loss**, which is now a target of universal phenotypic screening of newborns in the United States. Because the audiologic screening techniques are not uniformly reliable for the desired early diagnosis and intervention, ancillary molecular genetic testing has been proposed (133). The most obvious target for such screening is the *GJB2* gene, encoding the cochlear hair cell protein connexin-26; mutations in this gene are responsible for about half the cases of nonsyndromic autosomal recessive hearing loss. The mutation carrier frequency in the general population is about 3%, and there are predominant European Caucasian, Ashkenazi Jewish, and Asian mutant alleles. Molecular screening can be done using allele-specific techniques for these three high-frequency mutations or by complete gene sequencing for the more than 100 other variants, since the entire gene is only two exons. Some laboratories also test for a deletion in the neighboring *GJB6* (connexin-30) gene, which can interact with mutations in *GJB2* to cause hearing loss, even in the double heterozygote form. However, there are at least 100 other genes associated with hereditary hearing loss, and to develop a test encompassing them all requires either high-density microarrays or comprehensive next-generation sequencing of the entire gene panel (134,135).

Because of the presence of a founder mutation, 167delT, in the *GJB2* gene carried in as many as 10% of individuals of Ashkenazi Jewish descent, connexin mutation testing could also be added to the **Ashkenazi Jewish carrier screening panels** offered by a number of laboratories. These panels typically contain anywhere from 3 to 13 diseases, the most common ones being CF (carrier frequency in this population, 1/29), Tay–Sachs disease (1/27), Gaucher disease (1/15), Canavan disease (1/36), and familial disautonomia (1/30) (136). As in *GJB2*, the genes for these disorders feature between two and five predominant Ashkenazi mutations each, making screening technically easy and producing an aggregate yield of at least one positive carrier per six individuals tested (137). However, there are a few wrinkles that render the selected composition of the screening panel less than obvious. The most common Gaucher mutation, N370S, produces a fairly mild and late-onset phenotype (138), making decisions about pregnancy termination difficult. Tay–Sachs screening is successfully done by biochemical methods, so there is less impetus to incorporate it into a multiplex DNA panel. Canavan disease seems to be less common in some areas than its carrier frequency would suggest, and CF carrier screening is offered to all pregnant couples anyway, regardless of ethnic background (23).

If screening for connexin mutations becomes widely accepted, it would be the first example of a primary molecular approach in the **newborn screening** setting, since the other first-tier assays in newborn screening are biochemical in nature. However, DNA-based tests

have served as second-tier or follow-up tests for infants showing positive primary screens for CF or sickle cell disease in some states, and increasingly for other disorders in the expanded newborn screening panel. Still, any stand-alone molecular newborn screening test would have to meet the criteria of well-defined predictive value, a manageable number of predominant mutations, availability of a relatively inexpensive test methodology to pick up a significant proportion of them, and effective clinical interventions for those testing positive (136).

### 23.7 PHARMACOGENETIC TESTING

Another application of molecular genetic testing that could potentially involve large segments of the population is pharmacogenetic screening. At its broadest definition, the goal of pharmacogenetic testing is to identify mutations and polymorphisms throughout the genome that determine response and reaction to drugs. Presumably by their effects on drug metabolism and excretion, these genetic variants will identify those patients likely to respond or not respond to varying doses of the drug or to manifest adverse reactions to standard doses. Characterization of these genotypes prior to drug administration could hopefully enable individualized therapeutic approaches to maximize efficacy at the lowest possible dosage while avoiding side effects and toxicity. Pharmacogenetic tests may target germline variants, delineating heritable differences in drug response, or acquired, somatic mutations in tumors to predict response to chemotherapy; only the former application falls within the domain of medical genetics and is considered here.

The largest single class of enzymes involved in drug metabolism is the cytochrome P450 family of microsomal enzymes. SNPs in various members of this family, such as CYP2D6, CYP2C9, and CYP2C19, have been associated with impaired metabolism and hence toxicity of many important drugs, including codeine, haloperidol, propranolol, omeprazole, diazepam, amitriptyline, tamoxifen, clopidogrel, and warfarin (139). Testing for these variants is now possible on a variety of multiplex platforms, some of which are FDA approved. However, uptake by treating physicians has been quite low, owing in part to unfamiliarity but more importantly to the low predictive value of many of these genotypes (140).

Other potential pharmacogenetic targets are more narrowly drug specific. For example, the mitochondrial DNA mutation A1555G is known to confer increased sensitivity to the ototoxic side effects of aminoglycoside antibiotics (141). While not in routine practice because of other considerations surrounding the emergent use of these agents in the critical care setting, one might imagine pretreatment mitochondrial DNA testing for this variant if a rapid assay and alternative therapeutic strategies were available. A similar case could be made

for preoperative testing of patients for mutations in the ryanodine receptor gene *RYR1* as a screen for potential risk of malignant hyperthermia in response to common surgical anesthetics. The practicality of this approach is limited by the genetic heterogeneity of the disorder and evolution of anesthesiology practice beyond the former gas anesthetics like halothane. Still, a panel of 15 mutations has been recommended by a European consortium for testing at-risk family members (142).

The conceptualization of pharmacogenetic testing may even be expanded beyond traditional drug response to encompass other forms of therapy, such as radiotherapy. Heterozygote carriers of mutations in the *ATM* and related genes have increased sensitivity to therapeutic radiation, mirroring the more extreme radiosensitivity that is a hallmark of the affected patients with ataxia telangiectasia (112). With a carrier frequency of at least 1% in the general population, and the possibility that these carriers also have increased susceptibility to cancer, many of these individuals may find themselves facing radiotherapy sometime in their lives. A pretreatment screen for *ATM* and related mutations could identify those whose radiation dosage should be decreased in order to avoid severe tissue damage.

### 23.8 QUALITY ASSURANCE, REIMBURSEMENT, AND REGULATORY ISSUES

All clinical laboratories in the United States must adhere to the CLIA guidelines as a minimal level of quality assurance. Since all molecular genetic tests are considered “high complexity,” the regulations for that category must be followed. A problematic loophole has existed from the fact that molecular genetic tests had not been listed specifically in the existing CLIA regulations when written. For this reason, and because the CLIA regulations are seen as minimal standards, professional organizations have developed more detailed and rigorous practice guidelines. The most important are those of the ACMG, CAP, and the Clinical Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards), along with more general policy statements by the Association for Molecular Pathology (AMP). The CAP Molecular Pathology Checklist is particularly crucial since it is used for inspection and accreditation of those laboratories that choose to submit to this agency, which has been granted “deemed” status under CLIA. This checklist and the ACMG Standards and Guidelines for Clinical Genetics Laboratories are continually updated to reflect changes in techniques and maturation of the discipline, and the most recent versions are available on the respective organizations’ Websites (see next section). They contain many guidelines unique to molecular diagnostic laboratories, addressing issues such as PCR contamination, communication with genetic counselors, informed consent, interpretation

of mutational heterogeneity and sequence variants, molecular genetics personnel qualifications, technical procedures, appropriateness of test requests, and so on. While some have argued that it is not within the purview of laboratories to serve as gatekeepers for such matters as informed consent and appropriate test ordering, in practice it often falls to them since primary care providers may not be aware of such criteria.

Quality assurance (QA) encompasses all aspects of testing, from requisitions to specimen receipt through performance, interpretation, and reporting. In addition, recent initiatives by governmental and professional organizations have focused increasing attention on the need to include pre- and postanalytic factors within overall QA for genetic tests, especially those of a predictive nature. Tests must be validated both analytically and clinically prior to introduction, although that is often easier said than done, particularly for predisposition tests that may take decades to establish clinical predictive value. On the other hand, documentation of analytic validity has been assisted greatly by a continuing effort in partnership with the Center for Disease Control and Prevention (CDC), AMP, and the Coriell Cell Repositories to develop, characterize, and make generally available genomic DNA reference materials representing the most important alleles for genetic diseases and pharmacogenetic testing (143).

Another important component of QA is proficiency testing. This involves the regular shipment to laboratories of specimen unknowns that are analyzed, reported, and sometimes graded. CLIA mandates that laboratories participate in proficiency testing programs for each analyte they test, and if an organized formal program is not available, they must revert to other means such as informal sample exchanges with another laboratory or blinded retesting of previous samples. A successful and ever-expanding national program exists, codeveloped by CAP and ACMG and evolving in scope to address newer technologies like next-generation DNA sequencing. The performance of all participating laboratories is aggregated and provides a useful snapshot of the state of the art at any given time (144).

Reimbursement for molecular genetic testing has been a particularly frustrating issue for the laboratories. These tests tend to be relatively expensive and labor-intensive to perform and are often considered esoteric or experimental by third-party payers. Furthermore, since they are frequently performed on healthy individuals (e.g. in carrier screening for recessive mutations), the usual diagnostic/symptomatic indications for clinical laboratory testing are often absent. The acceptance and updating of essential procedural billing codes that more realistically represent the range and workload effort of modern molecular techniques was a step in the right direction, beginning with the addition of codes for such techniques as DNA sequencing, multiplex PCR, and mutation scanning some years ago (145), but it is a slow process. As

of 2012 there is a move to convert the method-specific codes like these that have always been used in molecular genetics (often “bundled” to reflex the ingredients of multiplex assays) to disease-specific codes (e.g. “CF”) as has always been the practice in molecular microbiology. There are both potential advantages and disadvantages to this approach.

Lastly, there is great concern that the whole field might be priced out of existence if mandatory royalties for use of patented genes and mutations in clinical laboratory tests inordinately add to the cost. Many of the genes discussed in this chapter have been patented, and various levels of exclusivity or sublicensing royalties are being enforced. Many laboratories of limited means have been forced to cease offering important molecular genetic tests because of restrictive gene patent conditions, and the situation can only get worse as next-generation sequencing technologies place all genes within reach of a single test. A number of lawsuits on this matter have been brought in US and European courts, perhaps the most publicized one contesting the constitutionality of the patents on the *BRCA1* and *BRCA2* genes (146). Even if these cases do not result in the global invalidation of gene patents, a program of reasonable royalties to allow access to clinically important gene targets would benefit both patients and laboratories by keeping prices down and allowing for peer comparison in performance across the genetic testing community.

## 23.9 INTERNET RESOURCES FOR MOLECULAR GENETIC TESTING

With the Human Genome Project producing an overwhelming information load and new genetic tests appearing almost every week, print sources in this field can never be up to date, and even if they were, it is difficult and time-consuming to extract the information needed, especially to answer an urgent clinical question. Fortunately, the genetics revolution has occurred at the same time as the informatics revolution, so computer technology can be used for rapid searching of relevant information that is constantly updated. The Internet offers many sites with useful medical genetics content; listed here are some of the key resources available to assist those ordering or performing molecular genetic tests.

### 23.9.1 Online Mendelian Inheritance in Man (OMIM)

(<http://www.ncbi.nlm.nih.gov/omim/>)—Most readers of this book will already be familiar with OMIM, the most comprehensive and up-to-date catalog of human genetic disorders available, currently boasting over 21,000 entries. Each disease entry includes, in addition to phenotypic features, information on the mapping and structure of the involved gene (where known) and its mutations.

### 23.9.2 GeneTests

(<http://www.ncbi.nlm.nih.gov/sites/GeneTests?db=GeneTests>)—GeneTests is the primary listing of genetic testing laboratories, searchable by disease (>2500 currently listed) or gene symbol. It is extremely useful for those facing a patient in need of an “orphan” genetic test for a rare disease, when one does not know where in the country (or the world) it might be offered. It is also an excellent referral source for more routine molecular genetic tests. Contact information for each laboratory is provided in order to address indications and requirements for testing prior to sending a specimen.

### 23.9.3 GeneReviews

(<http://www.ncbi.nlm.nih.gov/sites/GeneTests/review?db=GeneTests>)—GeneReviews is the sister site of GeneTests, providing detailed background material on the major disorders subject to molecular genetic testing, including information on clinical manifestations, the molecular pathology of the gene, and interpretation of DNA test results.

### 23.9.4 GeneCards

(<http://www.genecards.org/>)—GeneCards is structured like an encyclopedia, with entries on human genes, their protein products, variants and mutations, and their associated genetic disorders.

### 23.9.5 Human Gene Mutation Database

(<http://www.hgmd.cf.ac.uk/ac/index.php>)—Providing even finer detail, this database is the most comprehensive, continually updated listing of molecular alterations, currently cataloging over 85,000 reported mutations in over 3000 human genes. This database has become an even more essential reference for evaluating the thousands of nucleotide variants detected by whole-exome and whole-genome sequencing.

The Websites of professional and governmental organizations can also be useful, both as starting points for additional links and as sources of educational programs.

National Coalition for Health Professional Education in Genetics (<http://www.nchpeg.org/>)—This Website serves as a clearinghouse for a number of educationally oriented genetics information Websites as well as its own instructional material aimed for students and for non-genetic practitioners.

### 23.9.6 The Genetic Alliance

(<http://www.geneticalliance.org/>)—This is the best source for listings of patient support groups for genetic diseases, including many rare diseases (over 1000 currently represented); it is searchable by disease. The

Alliance is heavily involved in both advocacy and education.

### 23.9.7 College of American Pathologists

(<http://www.cap.org/apps/cap.portal>)—This Website contains the most up-to-date version of the Molecular Pathology Checklist for laboratory inspection, along with many other products and services relevant to QA and accreditation. Some content is open only to members.

### 23.9.8 American College of Medical Genetics

(<http://www.acmg.net//AM/Template.cfm?Section=Home3>)—This Website features its own updated Standards and Guidelines document and many policy statements related to molecular genetic testing, along with educational resources in various media. These cover both general testing issues and guidelines specific for individual diseases and include detailed descriptions of the available methodologies, appropriate use of the test, results interpretation, risk calculations, and reporting protocols.

### 23.9.10 Association for Molecular Pathology

(<http://www.amp.org/>)—The only organization devoted exclusively to molecular diagnostics, it is a source of information on technical and regulatory issues in the field. It also features its own laboratory test directory, focusing on non-genetic molecular tests not covered by GeneTests.

### 23.9.11 The DNA Learning Center

(<http://www.dnalc.org/>)—For those desiring a more basic introduction to the field, the DNA Learning Center, based at Cold Spring Harbor Laboratories, contains multimedia tutorials on introductory molecular biology concepts and history of the discipline.

## 23.10 SOCIETAL IMPACT OF THE NEW GENETIC TECHNOLOGY

The dawn of the twenty-first century has been called the beginning of the age of molecular medicine. Surely there can be no doubt that virtually every patient undergoing diagnosis or treatment in the coming decades will be involved in some sort of molecular genetic procedure. Even if it is on the treatment end (gene therapy), it will have been preceded by a molecular diagnostic procedure, since no patient can become a candidate for gene therapy until the precise molecular defect is known. Also certain is the fact that the diagnostic methods outlined in this chapter will become increasingly automated. As

DNA microarrays and other multiplex platforms become available as completely closed systems, free of complex hands-on manipulations and expert troubleshooting, they could just as easily move into the automated clinical chemistry laboratory as stay in the molecular genetics laboratory. Such a development would not necessarily serve the patients well, however, for even as the technical aspects of DNA tests become easier, their interpretation becomes more complex. Professional organizations have emphasized repeatedly that pre- and postanalytic aspects of genetic tests are just as important as the technical procedures themselves. Even if the technical portion is highly accurate and robust, much harm can ensue if the test was ordered inappropriately or the results information conveyed improperly.

With PCR, microarray, massively parallel sequencing, and other powerful technologies allowing ever more comprehensive genetic analyses on ever smaller and less invasive specimens, many complex issues surrounding genetic privacy and informed consent have arisen. Both governmental and professional organizations are attempting to address these concerns through safeguards in the testing process as stipulated in professional practice guidelines and legislation. Especially thorny have been the concerns surrounding predictive genetic testing in presently healthy individuals, since a positive test result carries risks of stigmatization, discrimination, anxiety, and depression. For these reasons, most professionals believe that specific informed consent and strict confidentiality are prudent for predictive testing. Furthermore, to assure appropriate ordering and results counseling for complex predictive tests, a case can be made that the laboratory should accept such orders primarily from genetics professionals or others with specific expertise in the field.

In the United States, more so than in other Western countries, the specter of insurance discrimination, which has been documented in limited numbers of patients (102,110,151), is often raised, impelling some patients to pay out of pocket for expensive tests so that their insurance carrier will not be aware of the result or even the fact that the patient was being tested. Yet, this raises other ethical issues such as inequitable access to testing, since only the economically well-off can afford to pay the cost themselves. Sometimes, however, these concerns become so blown out of proportion as to appear slightly irrational. Despite the hypothetical risk, most medical geneticists and genetic counselors would have a difficult time recalling even a single case in their experience of such blatant discrimination as loss of health insurance because of a genetic test result. Furthermore, we (and our patients) must always keep in mind the motivation for the test in the first place. For example, a woman may wish to pay for a predictive BRCA test out of pocket to keep the results secret from the insurance carrier, but if she tests positive and then desires a prophylactic mastectomy or oophorectomy, is she intending to pay for

the costs of surgery out of pocket also? Probably not, and yet she cannot expect the insurance company to pay unless it is aware of the indication for surgery, which is the positive test result itself. Such patients can be somewhat reassured by the passage of the Genetic Information Nondiscrimination Act by the US Congress in 2008 (147), although the actual extent of protection from this legislation remains to be tested in actual cases.

All these dilemmas remain moving targets because of the continuing march ahead of technology. The advent of next-generation sequencing, placing the entire genome or exome of a patient within reach for less than the price of sequencing of two or three individual genes, probably represents the greatest sea-change in molecular diagnostics since the innovation of PCR in the mid-1980s. Will comprehensive sequencing soon supplant all other targeted gene tests and screens? Will a drop of blood from every newborn be used for whole-genome sequencing in addition to or instead of the traditional biochemical screens for metabolic disorders? Or, taking it one step further, will pan-genomic screening be done in utero, or noninvasively using free fetal DNA circulating in the maternal blood as has recently been shown feasible (3,4,148)? Could the availability of these less physically invasive methods of prenatal diagnosis, as well as less emotionally invasive methods such as preimplantation genetic diagnosis, lead to a more cavalier attitude toward the use of molecular genetic technology to select for traits not directly related to disease?

Aside from the obvious ethical concerns in such scenarios, we should always remain aware of the limitations of molecular genetic testing, no matter how sophisticated the technology. Single genes and mutations rarely act entirely alone, and complex disorders clearly involve hundreds or perhaps thousands of genes all interacting at the DNA, RNA, and protein levels and with the outside environment. Thus, no DNA test, no matter how comprehensive, can ever tell the whole story. As the initial phase of the Human Genome Project is completed and we move on to the “postgenomic” or “proteomics” era, we will need to begin to think of genetic disease pathogenesis on a more “three-dimensional” level, taking into account the many interacting gene products in the nucleus and cytoplasm, as opposed to merely the “one-dimensional” string of nucleotides on a stretch of DNA. Whether tests of such phenomena, once they arrive, will be part of the domain of the molecular genetics laboratory or will move into a new “proteomics” laboratory section is anyone’s guess. However, as we await such advances, we can remain confident that the molecular genetic tests of today, and those added to the menu with each passing month, already offer a tremendous and irreplaceable service to many patients and their families, providing information and choices for their own lives and those of their offspring that had never been available before, in any form, in the entire history of medicine.

### Biography

**Joshua Deignan, PhD** is an Assistant Professor in the Department of Pathology and Laboratory Medicine in the David Geffen School of Medicine at UCLA. He is the Associate Director of both the Diagnostic Molecular Pathology Laboratory and the Orphan Disease Testing Center at UCLA. He did his undergraduate work in genetics at the University of California Davis, and he received his PhD in Pathology and completed his medical genetics fellowship training at UCLA. He is board-certified by the American Board of Medical Genetics (Clinical Molecular Genetics) and is licensed by the state of California as a Clinical Genetic Molecular Biologist Scientist.

### 24.1 INTRODUCTION

The specific biochemical or genetic abnormality in nearly 3000 genetic diseases in man has been determined (1). Most of these are transmitted with simple either autosomal- or X-linked-recessive patterns of inheritance. The ability to identify such conditions from affected individuals (probands) permits the rapid and accurate diagnosis of such disorders. Many of these methods have also been applied to permit detection of such disorders in the fetus during early gestation. Such approaches can provide vital options in genetic counseling for many families. The delineation of the underlying metabolic defect has also enabled investigators to develop rational and effective therapies for a variety of these disorders (2–4). In addition to the diagnostic and possible therapeutic implications of such discoveries, comparable methodologies have been employed for the detection of heterozygous carriers of many of the recessive traits involved. Accordingly, not only is a striking deficiency of enzymatic activity, gene dosage, or metabolic dysfunction evident in the diagnosis of the homozygous or hemizygous state (the affected male with an X-linked-recessive disorder) but also a distinct quantitative decrease of the same function can be demonstrated in the otherwise normal individual carrying the recessive allele. This capability to quantify gene dosage, and thereby to identify carriers of recessive traits, has been reported for many of the inborn errors of metabolism where the primary defect is known.

Advances in the applications of molecular genetic techniques have made it possible to identify (either directly or indirectly) heterozygous carriers of an increasing number of mutant alleles. In some instances this may involve direct detection of the mutation (e.g. sickle-cell trait or carriers of mutations for  $\beta$ -thalassemia, cystic fibrosis (CF), Tay–Sachs disease (TSD), and fragile X syndrome). In some conditions where the gene has eluded isolation

to date, or where extensive allelic heterogeneity still limits direct mutation detection, carrier identification has been achieved with the use of very highly polymorphic genetic markers (e.g. short tandem repeats (STRs)) segregating in specific families linked very closely to the disease-associated gene (e.g. Duchenne muscular dystrophy (DMD), hemophilia A).

It is not our intent in this chapter to review all known disorders and their current status regarding carrier detection. Rather, specific disorders will be cited as illustrative examples of the issue being discussed. Other chapters in this text more fully elaborate the fundamental inborn errors associated with such disorders or deal specifically with issues of prenatal and neonatal screening as well as heterozygote detection. It is also important to make the distinction between individual heterozygote testing and carrier screening. Heterozygote testing is the use of specific assays to determine the genetic status of individuals already suspected to be at higher risk for an inherited disorder because of a family history or clinical symptoms (5). In contrast, population-based carrier screening is the use of genetic tests to evaluate specific populations or groups of individuals independent of a family history of a disorder and without clinical symptoms.

### 24.2 CARRIER SCREENING IN CLINICAL PRACTICE

#### 24.2.1 To Prevent Anxiety in Family Members

When a patient is identified with a genetic defect or the family history reveals such a disorder in a close blood relative, the question of whether to test that individual and other family members for heterozygosity should be considered. In many instances where such tests are available and accurate, this can serve to reduce expressed or

hidden anxieties in other family members. Since most of these disorders are individually rare, it is relatively unlikely that other family members need be too fearful of producing affected offspring. For example, taking a maximum risk situation, an African-American individual whose brother or sister is a patient with sickle-cell anemia may be concerned about having affected children. Assuming they reproduce with another African-American person with no known sickle-cell anemia in the family, what are the actual risks? The unaffected sib (obviously not SS) of a person with sickle-cell anemia has two chances in three of having sickle trait (if born of the same parents as the patient with sickle-cell anemia). The approximate overall sickle trait frequency in African-Americans is about 1 in 10. Therefore, the likelihood that this person will be at risk for sickle-cell anemia in his or her offspring is  $2/3 \times 1/10 = 1/15$ . The likelihood that any given pregnancy will result in a child with sickle-cell anemia is  $1/4$  of that risk, or 1 in 60.

### 24.2.2 To Prevent Subsequent Intrafamilial Cases of Disease

Although these statistics alone can be somewhat comforting, simple carrier detection studies in the appropriate persons can put this question out of the realm of “calculation” and definitively establish if one or both individuals are carriers. If both prospective parents are found to be carriers, then comprehensive genetic counseling with a complete discussion of all available options can be initiated, including prenatal diagnosis, gamete donation (e.g. sperm or ovum from an established non-carrier donor), preimplantation testing, etc. Where at-risk couples are identified, this can lead to prevention of subsequent intrafamilial cases of disease—a second major reason to consider carrier testing in such families.

### 24.2.3 Marital Counseling

A third rationale for carrier screening relates to marital counseling, particularly where consanguinity between prospective parents may exist. Because of religious, moral, or other concerns, individuals might also use information about their carrier status in their decision regarding mate selection. This is the practice in certain Hassidic Jewish communities where strong religious prescriptions against abortion exist (6). Since marriages are “arranged” (often in childhood) and require rabbinical approval, some rabbis have opted for TSD carrier testing among the children or adolescents of their community (7). Approval for marriage is withheld by the rabbi (to whom solely the results of carrier testing are conveyed) if two carriers are “matched.” Alternative “arrangements” are then made without specifying the reason, thus avoiding family or individual stigmatization. While appropriate for individuals of this autocratic socioreligious belief system, generalization of this approach to other

individuals or groups is likely to be highly problematic. However, this paradigm has been expanded with the inclusion of carrier tests for several other diseases that are also found more frequently among the Ashkenazi Jewish population including Canavan disease, CF, and type I Gaucher disease, to name a few (8,9).

Currently, the American College of Obstetricians and Gynecologists (ACOG) (10) recommends that individuals of eastern European Jewish ancestry be offered carrier screening for CF, TSD, Canavan disease, and familial dysautonomia. In addition, individuals of Ashkenazi Jewish ancestry may inquire about screening for mucopolidosis IV, Niemann–Pick disease type A, Fanconi anemia group C, Bloom syndrome, and Gaucher disease.

### 24.2.4 Artificial Insemination or Ovum Donation

Another important consideration for carrier testing is where assisted reproductive technology is being considered by a couple as an alternative reproductive strategy to avoid the birth of a child affected with an autosomal-recessive or X-linked disorder. Nearly 3 in every 100 births in the United States are the result of some form of assisted conception (11). Potential sperm or ovum donors should be evaluated (where feasible and practical) by appropriate carrier screening tests to avoid what otherwise could be a most unfortunate tragedy. The authors are aware of two children with TSD, conceived by artificial insemination, born to two unrelated families who were attempting to have an unaffected child after they had had a previous child with this fatal condition. In another instance, screening of three medical students as potential sperm donors for a woman who had been previously identified as a TSD heterozygote showed one of the three to be a TSD carrier also. Of course, he was excluded as a potential donor. A recent survey of public sperm donor banks across the United States showed significant variation in the type of genetic testing performed on sperm donors (12). For example, CF carrier screening, hemoglobin evaluations, and chromosome analyses were performed on the majority of sperm donors. However, none of these sperm banks offered carrier screening for spinal muscular atrophy (SMA). Finally, less than half the surveyed sperm banks (37.5%) had a genetics professional on their staff. Such screening, in addition to a thorough family history on all potential gamete donors for other relevant issues, can help avert tragedy.

## 24.3 CARRIER SCREENING IN INDIVIDUALS OF DEFINED SUBPOPULATION GROUPS

A list of relatively “common” autosomal-recessive disorders (Table 24-1) seen in defined subpopulations in the United States is presented with data indicating the respective carrier frequency and newborn disease incidence in

**TABLE 24-1 Frequency and Incidence for Selected Autosomal-Recessive Disorders in Defined Ethnic Groups in the United States**

Disease	Ethnic Group	Gene Frequency	Carrier Frequency	"At-Risk" Couple Frequency <sup>a</sup>	Disease Incidence in Newborns
Sickle-cell anemia	African-Americans	0.040	0.080	1:150	1:600
Tay-Sachs disease	Ashkenazi Jews	0.016	0.032	1:900	1:3600
$\beta$ -Thalassemia	Greeks, Italians	0.016	0.032	1:900	1:3600
$\alpha$ -Thalassemia	Southeast Asians and Chinese	0.020	0.040	1:625	1:2500
Cystic fibrosis	Northern Europeans	0.020	0.040	1:625	1:2500
Spinal muscular atrophy	Asian	0.010	0.020	1:2500	1:10,000
Phenylketonuria	Northern Europeans	0.008	0.016	1:4000	1:16,000

<sup>a</sup>Likelihood that both members of a couple are heterozygous for the same recessive allele (assuming nonconsanguinity and that both are of the same ethnic group).

those ethnic groups. Gene frequencies and incidence of the disorder may vary considerably in the same ethnic groups in other parts of the world. The fact that selected genetic diseases occur predominantly in certain ethnic, religious, or racial groups is not surprising when one considers the relatively high degree of inbreeding seen in defined subpopulations (13,14). In addition to inbreeding, in some situations, selective environmental factors may have existed at some point in history that provided a biological (reproductive) advantage to carriers of the recessive gene (e.g. relative resistance to malaria in individuals who are heterozygous for sickle-cell hemoglobin,  $\beta$ -thalassemia, or glucose-6-phosphate dehydrogenase (G6PD) deficiency). Because of this selective effect, the gene becomes "enriched" from one generation to the next in that population.

It should be emphasized that while many of these diseases are relatively rare, the frequency of carriers can be quite high. For example, the disease incidence of CF among Caucasians of Northern European ancestry is approximately 1 in 2500 newborns, yet nearly 1 in 25 such individuals are carriers of a CF mutation. Similarly, the disease incidence for TSD among Ashkenazi Jewish newborns is about 1 in 3600, while the carrier rate in this population is approximately 1 in 30. Because of these population distributions and the availability of relatively simple, accurate, and inexpensive carrier detection methods, it is possible to screen individuals in these groups and identify persons and, more critically, couples at risk for homozygous disease in their offspring before affected children are born. With comprehensive genetic counseling, and the important options that prenatal diagnosis can provide, many "at-risk" families, identified through screening such subpopulations, might choose to have only children unaffected with the disorder for which they are found at risk.

For those relatively "common" autosomal disorders that occur within defined ethnic groups, there is usually no known prior history of the disease on either side of the family. Such a positive history may be present in only 20% of instances where a child with such a disorder is

diagnosed. For this reason, clinicians should consider carrier screening for all individuals in these subpopulation groups where heterozygote detection is readily available. Certainly, such testing and its implications should be thoroughly discussed with the patients, or they can be referred to appropriate regional agencies for such services. This is not only considered optimal preventive medicine but also has become the standard of care in many cases (10,15).

### 24.3.1 Tay-Sachs Disease

Perhaps the most effective effort of this nature has been the experience with TSD carrier screening and prenatal diagnosis (16–18). From 1970 (when serum carrier detection methods were first described) to 1999, community-based TSD education–screening–counseling programs have been initiated in Jewish communities throughout North America, as well as in Israel, South Africa, Europe, South America, and Australia. More than 1.4 million adults have been screened voluntarily and over 51,000 heterozygotes detected. Most critically, nearly 1400 couples—none of whom had an affected child previously—have been identified as being at risk for this fatal disorder in their offspring. Over 3200 pregnancies at risk for TSD have been monitored by amniocentesis or chorionic villus sampling, and the births of more than 625 affected infants destined to die with this disorder have been prevented. More importantly, this approach has been associated with the birth of over 2550 healthy infants. Overall, these efforts have contributed to more than a 95% decline since 1970 in the incidence of this disorder in Jewish infants throughout North America (6,17,19).

### 24.3.2 Beta-Thalassemia

Similar efforts directed at the prevention of  $\beta$ -thalassemia through education, carrier screening, and prenatal diagnosis have been initiated in several European countries and certain areas of North America. These programs

have dramatically reduced the newborn incidence of  $\beta$ -thalassemia in several Mediterranean countries (20,21). The highest incidences are reported in Cyprus (14%) and Sardinia (12%) (22). In Sardinia, for example, these preventative measures have reduced the incidence of disease by more than 94% of the prescreening levels (23).

### 24.3.3 Sickle-Cell Anemia

Screening for sickle-cell trait has been initiated in several parts of the world (including the United States). Although the capability to diagnose homozygous sickle-cell anemia in early fetal life is well established, through either amniocentesis or chorionic villus sampling, this alternative has not been widely adopted. This may reflect (at least in the United States) some of the complex sociopolitical issues associated with genetic screening of minority populations. However, in the United Kingdom, universal screening (both antenatal and neonatal) is recommended in regions where the populations comprise 15% or greater of the ethnic groups that are at risk for sickle-cell disorders (24).

### 24.3.4 Cystic Fibrosis

The American College of Medical Genetics (ACMG) and the ACOG published guidelines in 2001 for the screening of CF in the general population using a panethnic panel of 25 cystic fibrosis transmembrane conductance regulator (CFTR) mutations and several polymorphisms (25,26). These particular mutations were included in the panel because they had a  $>0.1\%$  frequency in CF patients. Another round of data review was initiated in 2002 because the initial results of large-scale screening with this panel revealed that some of the mutations initially included on this panel either were less frequent than originally thought (1078delT) (27) or were in fact polymorphic variants (I148T) when not coupled with a rare disease-causing mutation (3199del6) (28). Because of these initial shortcomings in the CF carrier screening panel, the ACMG just updated the panel (15), and this points out the value in designing and continually monitoring a large-scale carrier screening program from the very outset. Strom et al. (29) reviewed the performance of the ACMG/ACOG core CF panel in a clinical database of approximately 3 million carrier screen results and more than 2000 extensive sequencing analyses and suggest that this panel is performing as expected. These data show detection of approximately 90% of non-Hispanic white CF carriers and 77% of CF carriers in a US panethnic population (consisting of 64% non-Hispanic whites, 16% Hispanic Americans, 14% African-Americans, 5% Asian Americans, and 1% Ashkenazi Jews).

### 24.3.5 Spinal Muscular Atrophy

SMA is the most common fatal hereditary disease among newborns and infants worldwide and affects about 1 in

10,000 live births (30). This disease is caused by mutations in the survival motor neuron (*SMN1*) gene and affected patients demonstrate the homozygous deletion of *SMN1* exon 7 in most cases (31). Carrier frequency is on the order of 1:40 to 1:60, with the highest carrier frequency seen in Caucasians (1:35) and the lowest in Hispanic populations (1:117) (32). Although no treatment is currently available for SMA, carrier detection is feasible and is estimated to have a detection rate of about 90% within most populations (33). Universal carrier screening for SMA was recommended in 2008 by the ACMG (30).

## 24.4 THERAPEUTIC IMPLICATIONS FOR HETEROZYGOTES

Although in most instances heterozygosity for a recessive trait is of no known health consequence to the individual, there are conditions in which the heterozygous state may impart certain health hazards. These concerns discussed below pertain primarily to carriers of autosomal-recessive genes and heterozygotes of X-linked disorders, which may well have therapeutic issues depending on the disorder and lyonization. Accordingly, for these individuals, knowledge of their carrier status may have therapeutic or preventive health implications. For example, persons with AS hemoglobin (sickle-cell trait) should be aware of the possible hazards of exposure to reduced ambient oxygen concentrations (e.g. mountain climbing at high altitude, flying in an unpressurized aircraft above 8000 feet) (34). In addition, alerting the anesthetist of the AS trait of the patient prior to gaseous anesthesia could avert inadvertent hypoxia, which might be particularly hazardous to such an individual. Heterozygous individuals for type II hypercholesterolemia may be predisposed to premature atherosclerotic degeneration and coronary artery insufficiency. Appropriate therapy (diet, weight control and/or specific medication) may reduce the risk for early myocardial infarction in individuals carrying this dominantly expressed disorder. In a similar fashion, persons heterozygous for alpha-1-antitrypsin deficiency (MZ) may be predisposed to chronic obstructive pulmonary disease in early adulthood. Avoidance of tobacco smoke and other noxious inhalants may greatly reduce this risk. Having identified an individual as heterozygous for this mutation, it might be of great practical value for this person to be counseled and guided into appropriate job selection and/or environmentally safe areas, as well as informed of the particular importance of not smoking.

## 24.5 METHODS AND TISSUES USED IN CARRIER IDENTIFICATION

Depending on the genetic nature of the condition, its expression in different organ systems, and the availability of appropriate material for examination, a variety of approaches have been used historically for heterozygote detection. These approaches ranged from physiological

studies to direct mutation analysis. For example, somatic cell methods assessing the enzymatic (HPRTase) or physiological ( $^3\text{H}$ -hypoxanthine incorporation) properties of clones of skin fibroblast cells were useful in the past for carrier detection in Lesch–Nyhan syndrome. However, molecular genetic techniques including direct mutation detection have replaced this approach to carrier identification for this disorder (35). Newer methods for DMD carrier testing include quantitative polymerase chain reaction (PCR) methods followed by DNA sequencing of the dystrophin gene, and these methods offer advantages over the more classical approach using a combination of pedigree analysis, serum creatine kinase levels and linkage analyses to assess an individual's carrier status (36).

### 24.5.1 Molecular Genetic Techniques

A variety of molecular genetic techniques are used for direct mutation detection in the heterozygote (Table 24-2). In general, these are PCR-based methods to scan or screen small exon-sized DNA fragments for point mutations or small (e.g. 3–5 base pair) insertions or deletions. Direct sequencing methods are commonly used for direct mutation detection in CF,  $\beta$ -thalassemia, and other disorders. Extremely large insertions, deletions, or other rearrangements are still best detected with Southern blotting, as is the case for the common deletions in  $\alpha$ -thalassemia or the larger premutations and full expansion mutations in fragile X syndrome. In some instances a combination of DNA-based methods may be used to optimize carrier detection. For example, carrier identification for fragile X syndrome may involve

a combination of Southern blotting and PCR to reliably detect the full spectrum of expansion mutations observed within the *FMR-1* gene (37). In many laboratories, mutation detection for relatively small genes such as beta-globin has moved from PCR and allele-specific oligonucleotide hybridization to direct sequence-based methods using semiautomated capillary electrophoresis systems. In some laboratories, the sequencing of large genes including CFTR is now becoming routine.

### 24.5.2 Tissues Used for Heterozygote Detection

Historically, tissues used for heterozygote detection in representative recessive disorders are presented in Table 24-3. In considering carrier detection (either testing an individual or screening a subpopulation), the accessibility of appropriate tissue or material for testing influences the feasibility and cost of such procedures. In some instances, accurate heterozygote identification can be achieved with readily available tissues such as serum, circulating blood cells, buccal epithelial cells, or tears. In other cases, optimal carrier detection may require cultured skin fibroblasts or even biopsied liver or muscle tissue. Clearly, whether to conduct such studies in individuals related to an affected person, or more generally, will be strongly influenced by such considerations.

### 24.5.3 DNA-Based Techniques

The application of DNA-based techniques in the detection of mutant genes has had great impact on this issue. Since adequate DNA samples are readily obtained from a routine blood sample, the aforementioned reservations are in large part obviated if “DNA methods” can be employed. In some instances, DNA from buccal cells rinsed from the mouth (or even the amount extracted from a single somatic cell) in conjunction with PCR-based methods may provide sufficient material for carrier testing purposes. These PCR-based procedures can be performed more quickly and easily than Southern blot hybridization methods. In addition, PCR methods can be used on small amounts of genomic DNA present on dried blood spots. Accordingly, ease of testing as well as ultimate cost (particularly since such methods are readily automated) should allow for greatly expanded carrier testing for these disorders.

TABLE 24-2 Selected Molecular Genetic Techniques Used for Direct Mutation Detection and Heterozygote Identification	
Method	Representative Disorders
Restriction enzyme digestion of PCR products	CF, FV Leiden TSD
Allele-specific oligonucleotide hybridization	CF, $\beta$ -thalassemia
Southern blotting	$\alpha$ -thalassemia, hemophilia A, fragile X syndrome
Reverse dot blot hybridization, oligonucleotide	CF
Ligation assay (OLA)	
Denaturing gradient gel electrophoresis (DGGE)	Hemophilia A, CF
Single strand conformation polymorphism (SSCP) analysis	Hemophilia B
Multiplex ligation-dependent probe amplification (MLPA)	DMD
Direct DNA sequencing of PCR-amplified DNA	$\beta$ -thalassemia, CF, DMD

CF, cystic fibrosis; TSD, Tay–Sachs disease; DMD, Duchenne muscular dystrophy.

## 24.6 PROBLEMS IN HETEROZYGOTE DETECTION

### 24.6.1 Statistical Constraints

The great majority of the inborn errors of metabolism are relatively rare conditions. Although in the aggregate it is estimated that perhaps 1% of all live-born infants

**TABLE 24-3** Tissues Historically Used for Carrier Detection in Representative Autosomal-Recessive Disorders

Tissue	Methods	Disorder
Serum, plasma	Enzyme assay, immunoquantitation, functional assay	TSD, hemophilias
Erythrocytes	Enzyme assay, electrophoresis	G6PD deficiency, hemoglobinopathies
Leucocytes	Enzyme assay, histology, functional tests	Gaucher, Batten, CGD, Lesch–Nyhan
Skin fibroblasts	Enzyme assay, cell cloning	MLD, Hunter
Hair follicles	Enzyme assay/ratio	Lesch–Nyhan, Fabry disease
Tears	Enzyme assay	TSD
Teeth	Vertical banding	Amelogenesis imperfecta-XR
Eyes	Fundoscopy	XR-fundal dystrophies, RP
Liver, muscle biopsy	Enzyme assay, histology	OTC, DMD
DNA from somatic cells	Direct mutation detection, linkage	Hemoglobinopathies, CF, DMD, hemophilias, CF

TSD, Tay–Sachs disease; CGD, chronic granulomatous disease; OTC, ornithine transcarbamylase deficiency; CF, cystic fibrosis; MLD, metachromatic leukodystrophy; DMD, Duchenne muscular dystrophy; RP, retinitis pigmentosa; G6PD, glucose-6-phosphate dehydrogenase.

will, at some time in life, manifest such a single-gene disorder, there are thousands of such disorders now recognized (1). This poses critical problems for carrier identification. The only individuals who are obligatory carriers of an autosomal-recessive genetic trait are the biological parents of an affected individual (discounting the  $10^{-5}$ – $10^{-6}$  possibility of new mutation). Therefore, in the establishment of a carrier identification method, it is critical that a “significant number” of such obligatory heterozygotes be studied (and control individuals as well) before statistical validity can be assigned to the testing method. In this regard, one must be careful in interpreting research publications in which only small numbers of obligate heterozygotes have been tested and where results suggest that the methods are applicable to carrier detection. Obviously, the larger number of samples of obligate carriers and controls, and the greater the separation observed in the test results between the two groups, the greater the likelihood for significant applications of the method to heterozygote identification.

It is a very different matter to study persons who the investigator knows must be carriers for a particular trait than individuals who are complete unknowns. Essentially all prior experience with nonmolecular methods

used in carrier detection reveals a variable distribution of test results both for carriers and controls. The narrowness of each distribution and the degree of separation between them are critical in assigning a statistical probability that any given test result falls into one or the other distribution.

With molecular methods, however, these constraints are obviated in large part. Certainly, where direct mutation detection is possible, carrier detection is evident without the need for massive numbers in control studies or expansive statistical determinations. With the use of restriction fragment length polymorphisms or STRs, on the other hand, the proximity of the polymorphic marker to the disease locus is critical to interpretation, since possible meiotic crossover events can confound apparent conclusions drawn by linkage analysis.

### 24.6.2 Why Variability?

One would expect that individuals who are heterozygotes for an autosomal-recessive mutation would reflect 50% of the value (whatever the measurement happens to be) of that found in homozygous normal persons. This is clearly not the case. Not only is there variability of test values in heterozygotes but considerable variation may also be evident in data obtained from normals. This may reflect the limitations of the methods employed and/or the inherent biological variability of such functions. Other genetic and environmental factors may influence any given biological parameter such that a range of results is seen in carriers and noncarriers. In some instances where, for example, an enzymatic activity measurement is the test employed, there may be levels of activity in heterozygotes distinctly less than 50% of normal. Where the relevant enzyme is composed of multiple subunits—only one of which is under control of the gene in question—random aggregation of normal and abnormal subunits can result in a wide range of activities in the multimeric enzyme. Other mutations may result in only partial reduction in activity of the respective polypeptide. In this instance, the heterozygote may have near-normal activity or activity that overlaps considerably with the range of measurements found in noncarriers.

With X-linked conditions, the carrier female reflects a broad range of test results extending from clearly normal levels to those seen in affected males. This is predominantly a manifestation of the well-known lyonization effect with X chromosome-linked genes. This biological phenomenon can make carrier determination for such X-linked genes difficult. In fact, heterozygous females who carry X-linked-recessive genes are mosaic in the expression of most of the genes in question, with a certain proportion of their somatic cells expressing the normal gene and the remainder reflecting the mutant state. The reader is referred to other chapters in this volume concerning specific

X-linked disorders for further discussion of carrier-state identification.

### 24.6.3 Other Factors Influencing the Carrier Test

In addition to the consideration that other genes in an individual's constitution may modify the expression of a distant specific gene locus, other biological factors may influence gene expression as well. Factors such as age, pregnancy, drugs and medications and certain illnesses might influence the parameter in question, thereby altering the ability to distinguish carriers from noncarriers. Such issues need to be addressed before wide-scale application of a carrier detection method is made.

**24.6.3.1 Genetic Heterogeneity.** Genetic heterogeneity is an important factor in identifying carriers of mutant genes. Two types of heterogeneity are recognized: genetic heterogeneity and allelic diversity. Genetic heterogeneity can be defined as mutations at two or more genetic loci that produce the same or similar phenotypes (either biochemical or clinical). This is relevant since genetic heterogeneity can present problems for heterozygote detection. For example, forms of Ehlers–Danlos syndrome, a disease of the connective tissue, are known to result from alterations at multiple genes inherited with autosomal-dominant, autosomal-recessive, and X-linked-recessive patterns of inheritance. Similarly, the multiple complementation groups in methylmalonic acidemia also indicate genetic heterogeneity for this condition. Many other examples exist as well. Linkage analysis for the purposes of carrier detection and prenatal diagnosis should be used with extreme caution in disorders where evidence exists for genetic heterogeneity.

Allelic diversity is the presence of more than one mutation within the same gene that may be associated with highly similar, or very different, biochemical or clinical phenotypes. This has obvious relevance for heterozygote detection. For example, if a standard hemoglobin electrophoresis result (biochemical phenotype) is the only parameter used for sickle-cell trait identification, then persons carrying the mutation for hemoglobin-D will be incorrectly identified as carriers of the sickle-cell trait since the S and D hemoglobins electrophorese similarly under standard conditions. In this instance, of course, the adjunct use of other methods, such as hemoglobin solubility studies or sickling on deoxygenation, will clarify this possible discrepancy. Similarly, one must be able to differentiate the mutations associated with hemoglobins S and C when performing DNA-based diagnosis of the sickle-cell trait. Allelic diversity is also an important consideration in disorders such as CF, hemophilia A, and  $\beta$ -thalassemia. Direct mutation analysis in these disorders for only a subset of specific mutations may fail to detect a different disease-causing mutation in a particular family, which may have critical genetic counseling implications for many individuals within that pedigree.

**24.6.3.2 Benign or Pseudodeficient Mutant Alleles.** Benign or pseudodeficient mutant alleles are additional examples of allelic diversity with important implications for carrier detection and genetic counseling. These are mutations that mimic the true disease-related carrier state but are not associated with abnormal clinical phenotypes. Such mutations are relatively common in the genes directing the synthesis of various lysosomal hydrolyses (38). In these disorders, enzyme-based screening tests will fail to distinguish carriers of a disease-causing mutation from carriers of a benign or pseudodeficient allele. For example, in TSD screening, the enzymatic test employs an artificial substrate in carrier identification. Deficient enzymatic activity is observed both in carriers of pseudodeficient mutations as well as in carriers of disease-related mutations (19). These pseudodeficient mutations, however, are not associated with TSD or any known clinical abnormalities. Two such pseudodeficient alleles are the most common mutations found among the enzyme-defined “carriers” of TSD in non-Jewish populations. To distinguish true carriers from carriers of pseudodeficient mutations, DNA-based testing is indicated.

Accordingly, DNA testing should be employed after the enzymatic determination of the carrier state in all non-Jewish individuals and all couples who are identified as at risk (both carriers), regardless of religion. This has obvious implications for accurate genetic counseling and prenatal diagnostic decisions (19,39). To conduct primary screening with DNA-based testing alone would miss a significant number of carriers and would not be cost effective. Rather, sequential use of gene product and molecular methods in this way optimizes genetic counseling and prenatal diagnostic interpretations, as well as optimizing cost-effectiveness.

**24.6.3.3 Environmental Factors.** In some instances where nonmolecular methods for carrier detection are employed, certain environmental factors such as drugs, diet, or other agents could affect biological functions and thereby influence their applicability to carrier detection. Iron deficiency can cause hematological changes that mimic the findings of heterozygotes for  $\beta$ -thalassemia. Birth control medications and pregnancy have been shown to result in a relative reduction in serum hexosaminidase A levels, making many of these women appear as carriers for TSD (40). These are only two examples where such determinations can be influenced by external factors, resulting in inaccurate carrier identification studies.

## 24.7 SENSITIVITY AND SPECIFICITY

With all the above considerations in mind, and having assessed reasonable numbers of obligate heterozygotes and controls with the recommended method(s), significant overlap in the distribution of carriers and noncarriers may still remain. Capabilities of any one laboratory may not be comparable with those of others reflecting,

perhaps, differences in preferred methodologies or other inherent variables. Thus the ability to identify all true carriers (sensitivity) is reflected in the false negative frequency of the test employed. The identification of only true carriers (specificity), and not other persons with a false-positive test, is also of importance. The greater the overlap in distributions of values between carrier and noncarrier, the greater the likelihood for either or both types of misclassification.

The advantage of mutation-specific DNA-based testing is that extremely high levels of specificity are achieved. However, since such methods will identify only the specific mutations examined, a decrease in sensitivity is inherent because other mutations in the same gene will not be identified. Since most mutations within a gene affect the gene product, carrier test sensitivities are highest when gene product analysis is the testing method employed. Ideally, carrier screening should be done initially by gene product assay (e.g. enzyme, protein, messenger RNA) with its high sensitivity. High-specificity DNA-based methods can then be employed to confirm abnormal results, to rule out pseudodeficient states and to identify specific mutations that may have obvious implications for diagnosis or genetic counseling.

With nonmolecular carrier detection methods, even where a defined level of overlap is known to exist, carrier detection studies may still be appropriate. In this context, a test result clearly in the carrier range may indicate, with great likelihood, that the person is heterozygous, while a result in the overlap area would be less definitive and leave the carrier status indeterminate. Similarly, a result at the upper levels of the noncarrier distribution might make the probability of heterozygosity exceedingly small. Where such difficulties exist, carrier screening is best restricted to use only in high-risk individuals (close relatives of probands), rather than in more general or subpopulation screening. Only those approaches whose statistical reliability and accuracy and relative ease of applicability have been proved by prior studies should be candidates for more general use.

## 24.8 COST AND FEASIBILITY

Where significant morbidity or cost would be involved in performing carrier detection studies (even where the accuracy is optimal), these issues should be considered and discussed with the individual before proceeding. DNA-based methods usually can be employed with DNA extracted from readily available somatic cells (leukocytes, skin cells, buccal epithelial cells in saliva, etc.) and at reasonable cost.

## 24.9 AGE FOR CARRIER TESTING

Heterozygosity for most recessive traits has little if any health consequences for the individual and it is only a matter relevant to reproduction. For this reason, carrier

testing is best instituted just prior to, or during, the reproductive age. This has added benefits in that the person's ability to comprehend the meaning of such information is much more likely to be adequate at such an age. Likewise, carrier testing among children or young teenagers should not be undertaken routinely and should be considered only under special circumstances. One's level of maturity and background education may be important factors in obviating any possible stigmatization that carrier identification could entail. A parental request to determine the possible carrier status of their child(ren) need not be a sufficient basis to proceed. Rather, a full discussion with the parents as to the lack of health implications and possible psychosocial hazards of testing youngsters may lead to deferral of testing to a more appropriate time. With regard to adult-onset disorders, a committee of the American Academy of Pediatrics has recommended that persons 18 years of age or younger only be tested if testing will offer immediate benefits to the person being tested or another family member, and if there is no harm anticipated to the individual being tested (41).

## 24.10 CONCLUSIONS

From its very outset a number of complex and important social and ethical issues have been identified with genetic screening (5,42). Issues such as possible personal, familial, or even more general stigmatization of the identified carrier; maintenance of utmost confidentiality of test results; rigorous protection of individual privacy; and informed consent of the tested individual are but a few of the more important concerns raised. Clearly, the physician must consider all these matters in their interaction with the patient and families where possible genetic testing is anticipated.

The implementation of carrier screening programs must rely upon education and standardization. Both the affected population and health care providers need education about genetic screening programs. This is amply illustrated by the cumulative experiences of the TSD,  $\beta$ -thalassemia and CF carrier screening programs. Even if the individual tested receives a negative screening result, it will still be appropriate for the physician to order a diagnostic test if warranted by the clinical circumstances. Subpopulations affected by targeted carrier screening programs also need to be reliably informed about the mutation detection rates and overall clinical utility to ensure that genetic counseling is effective (5,18). Standardization will play an increasingly important role as carrier screening programs expand and new ones develop. Some have suggested that technologies could be standardized to just a few analytical testing platforms (5). In addition, carrier screening programs can borrow from the successes of newborn screening programs that exist in the United States and those around the world.

Heterozygote detection in the future will continue to rely heavily upon DNA-based methods including direct sequencing methods. In 2012, there were over 20,000 entries in the Online Mendelian Inheritance in Man database (1). We expect that novel methods will be developed that may involve the analysis of metabolite (e.g. peptide fragments) and gene products (e.g. enzyme). Furthermore, a variety of analytical testing platforms that have recently been developed may gain even more widespread use including but not limited to microarray and resequencing chips and massively parallel next-generation sequencing methods. Eventually, screening may involve the simultaneous analysis of multiple disease loci by almost completely automated methods. With appropriate technical, medical, and educational expertise, the expanded use of these new approaches in the future will serve to reduce the individual, familial, and societal burdens associated with many severe, and currently untreatable, hereditary disorders.

### Biographies

**Dr McGinniss** is senior director, Molecular Diagnostics at Caris Life Sciences. Prior to joining Caris Life Sciences, he was executive director, Laboratory Operations at Prometheus Laboratories in San Diego. Prior to that Dr McGinniss served as a senior director, Molecular Genetics for Quest Diagnostics Nichols Institute. He is board-certified in Clinical Molecular Genetics by the American Board of Medical Genetics and in Molecular Diagnostics by the American Board of Clinical Chemistry. Dr McGinniss holds a BA in Zoology from the University of New Hampshire, an MS in Zoology from Virginia Polytechnic Institute and State University, and a PhD in Cell Biology from the University of Vermont. He completed a postdoctoral research fellowship in pediatric genetics at the Johns Hopkins University School of Medicine. He is the author of 42 scientific papers and 4 book chapters/reviews.

**Dr Kaback** is professor Emeritus, Departments of Pediatrics and Reproductive Medicine, University of California, San Diego, School of Medicine. He is also a research scientist, Cedars-Sinai Medical Center, Los Angeles, California. He is best known for his role in the discovery and development of an enzyme assay method of screening for Tay–Sachs disease heterozygotes and pioneering community-based voluntary carrier screening programs throughout the world. For many years he was the Director of the State of California Tay–Sachs Disease Prevention program (1973–2006) and Director, International Tay–Sachs Disease Testing, Quality Control and Data Collection Center (1979–2006). Dr Kaback holds a BA from Haverford College and an MD from the University of Pennsylvania School of Medicine. He completed a residency in Pediatrics at the Johns Hopkins University School of Medicine. Dr Kaback is an elected member of the Institute of Medicine (National Academy of Sciences) and an elected fellow of the American Association for the Advancement of Science. He was awarded the William Allan Memorial Award in Human Genetics by the American Society of Human Genetics in 1993. Dr Kaback was the North American Editor of Prenatal Diagnosis (1979–2006). He was elected president of the American Society of Human Genetics (1991) and president of the American Pediatric Society (1998). He is the author of hundreds of scientific papers, over 14 book chapters/reviews, and several textbooks.

## Prenatal Screening for Neural Tube Defects and Aneuploidy

*Amelia L M Sutton and Joseph R Biggio*

Department of Obstetrics and Gynecology, Division of Maternal Fetal Medicine,  
Department of Genetics, University of Alabama at Birmingham, Birmingham, AL, USA

This article is a revision of the previous edition article by David A Aitken, Jennifer A Crossley and Kevin Spencer, volume 1, pp 636–678, © 2007, Elsevier Ltd.

### 25.1 INTRODUCTION

Neural tube defects (NTDs) and aneuploidies are major causes of perinatal death and childhood morbidity. Routine screening for these anomalies has become a standard part of prenatal care in many countries throughout the world. As with all screening programs, the screening tests seek to identify women at highest risk for the particular disorders of interest, who are in turn offered a more specific and frequently more expensive or invasive diagnostic test. Recent improvements in screening tests for aneuploidy has led to a dramatic shift in the practice patterns and a decline in the number of diagnostic tests, such as chorionic villus sampling (CVS) or amniocentesis, which can be associated with fetal loss. A combination of folate supplementation (both on an individual level and at a national level in grain products) for primary and secondary prevention and screening with maternal serum alpha-fetoprotein (AFP) followed by comprehensive ultrasound evaluation for screen-positive women, and termination of affected fetuses, has dramatically reduced the birth incidence of NTDs. The impact of prenatal screening and diagnosis on the incidence at birth of aneuploidy has been less profound and likely reflects changes in the maternal age distribution and social mores. Recent advances in combined first- and second-trimester screening strategies, utilizing both biochemical and ultrasound evaluation, have increased the detection rates of chromosomal abnormalities to such levels that many women elect to forego prenatal diagnostic procedures, resulting in reduction of rates of these procedures by more than 50% in many countries.

### 25.2 NEURAL TUBE DEFECTS

#### 25.2.1 Classification

Anencephaly and spina bifida comprise 90% of NTDs. All anencephaly cases and most spina bifida cases are

open lesions, classified by exposure of neural tissue and meninges, detectable by biochemical testing due to leakage of AFP from the fetal circulation. In contrast, closed lesions, in which skin covers the defect, are not detectable by biochemical assays. Only 15–20% of spina bifida cases are closed defects but, in general, the prognosis is more favorable. The remaining 10% of NTDs consists of encephalocele, in which there is herniation of neural tissue through a cranial defect, and iniencephaly, a condition characterized by severe head retroflexion, absent occiput, and fusion of the spinal and cranial cavities.

#### 25.2.2 Frequency and Occurrence

Worldwide, the incidence of NTDs is approximately 1–10 per 1000 births, with some geographic variation (1–3) (Table 25-1). Multiple studies in the 1990s established that adequate maternal folate levels are essential for normal fetal neural tube development and closure. After widespread dietary supplementation and fortification of food staples with folate in the United States, there was a 23% reduction in spina bifida in less than a decade (4). Despite these efforts, the incidence of myelomeningocele remains significant at 3.4 per 10,000 live births (5).

Approximately 90–95% of NTDs occur in women with no family history of the condition (6). There are several lines of evidence that support an underlying genetic, albeit heterogeneous, cause in NTD development. First, NTDs are associated with trisomy 13 and 18 among other chromosomal abnormalities (7). Second, in mothers with a previous NTD-affected pregnancy, the risk of recurrence in a subsequent pregnancy is 3%, representing more than 40-fold increase over the general population, with risks increasing further with each additional affected offspring or first-degree relative (8). Finally, more than 200 mouse models of NTDs have been developed with mutations in various genes (9).

**TABLE 25-1** Prevalence of Neural Tube Defects in Pregnancy

Country	Period	Crude Pregnancy Prevalence/10,000 <sup>a</sup>			
		Anencephaly	Spina Bifida	Encephalocele	Total

### 25.2.3 Prevention and Treatment

Regardless of treatment, the prognosis is poor for most large open NTDs. Neonates with anencephaly typically die within the first few days of birth and severe cases of myelomeningocele frequently end in spontaneous abortion. Neurologic function below the level of the lesion is typically impaired and survivors with myelomeningoceles usually experience paralysis, bowel and bladder dysfunction, and cognitive and developmental abnormalities. Multiple surgeries to correct the defect and to treat the consequent hydrocephalus with shunting typically are required. Cognitive abnormalities may be related to complications of shunting (e.g. ventriculitis due to shunt infections) or may be related to the underlying neurologic developmental abnormalities that lead to the defect in the first place. The IQ of children with repaired myelomeningocele is significantly lower than unaffected controls (10). NTDs are associated with alterations in the circulation of cerebrospinal fluid, resulting in ventriculomegaly and hindbrain herniation, which may be either secondary to the altered fluid dynamics or related to a primary defect in the development of the posterior fossa (11). Owing to morbidities associated with hydrocephaly and Arnold–Chiari malformations, ways of reducing postnatal complications have been investigated. The first in utero surgical correction of myelomeningocele was via an endoscopic technique in 1994 (12). All fetuses died in

this study, and so the technique was abandoned. Further efforts exploring the endoscopic approach were also met with disappointing results (13–15). Open prenatal correction of myelomeningocele was first performed in 1998 (16) and multiple observational studies reported salutary results with regard to neurologic function (17–22). Recently, a large multicenter randomized trial evaluating the efficacy and safety of prenatal surgery compared to standard postnatal surgery was reported (23). This study showed several favorable outcomes, including decreased risk of death or shunting at 1 year of age, lesser degrees of hindbrain herniation, and improved cognitive and motor function at 30 months of age. Prenatal surgery was associated with higher rates of preterm delivery, operative complications, and uterine dehiscence.

Dietary supplementation with folic acid is the primary means of preventing NTDs. A large multicenter randomized controlled trial demonstrated that periconceptional folate supplementation decreased the recurrence of NTDs in women with a prior affected pregnancy by approximately 70% (24). Studies have demonstrated that folic acid intake can also prevent primary occurrences of NTDs (25,26). The Centers of Disease Control recommends that women with a previously affected pregnancy take 4mg of folic acid daily before conception and throughout the first trimester (27) while others suggest that up to 5mg per day might be more effective (28).

The U.S. Public Health Service and the ACOG recommend that all women of reproductive age take 0.4 mg of folic acid daily (6). The timing of folate supplementation is critical as the neural tube is closed by 4–5 weeks of development (6–7 weeks menstrual age); thus, folic acid must be taken before conception and through the first trimester.

## 25.2.4 Prenatal Diagnosis of Neural Tube Defects

Identification of pregnancies affected by NTDs allows termination of the pregnancy, planning for postnatal care and surgery, or if appropriate, prenatal correction of the defect. Maternal serum alpha-fetoprotein (MSAFP) levels are elevated in most pregnancies affected by NTDs. Traditionally, women with elevated MSAFP were offered genetic amniocenteses with measurement of AFP and acetylcholinesterase in the amniotic fluid. Recent advances in ultrasound technology and imaging have dramatically changed the evaluation of screen-positive gestations, with diagnostic amniocentesis generally restricted to a subset of pregnancies.

**25.2.4.1 AFP in the Fetal Circulation.** AFP is produced by the fetal yolk sac and liver and is a major protein in the fetal circulation, with concentrations  $10^6$ -fold higher in the fetal circulation compared to the maternal circulation (Figure 25-1). The protein is freely filtered through fetal glomeruli, is present in fetal urine, and accumulates in the amniotic fluid with advancing gestation. AFP reaches the maternal serum by a combination of transplacental and transamniotic diffusion.

AFP can be easily and accurately measured by quantitative immunoassays. The serum concentration of AFP is gestational, age-dependent and peaks in the third

trimester; therefore, an accurate estimation of gestational age is essential for interpretation of the concentration (29). To account for variance between laboratories and the timing of specimens, concentrations are usually expressed as multiples of the median (MoM) of unaffected pregnancies at the specific gestational age and comparisons are then made using MoMs.

**25.2.4.2 Prenatal Screening for NTDs by MSAFP.** In the early 1970s, the relationship between elevated amniotic fluid levels of AFP and open NTDs was discovered (30). Later it was shown that maternal serum levels of AFP were also increased in affected pregnancies (31). Defects in fetal skin, including open NTDs and ventral wall abnormalities such as gastroschisis and omphalocele, cause increased amniotic fluid AFP concentrations by a direct transudative process (29). Fetal renal disease, intrauterine demise, and contamination of the amniotic fluid with fetal blood also result in elevated AFP concentrations (29).

Multiple large prospective trials have demonstrated that MSAFP testing represents an effective screening strategy (32–35). In a large study including over 18,000 unaffected and 300 affected pregnancies and MSAFP screening at 16–18 weeks, MSAFP levels of 2.5 MoM or greater detected 88% of anencephaly cases and 79% of spina bifida cases (35). Although there is considerable overlap between affected and unaffected pregnancies, a cutoff of 2.5 MoM was associated with just a 3% false-positive rate. Detection is enhanced when pregnancy dating criteria are based on a biparietal diameter measurement because fetal head size is smaller in the setting of an NTD. This results in a slight underestimation of the GA and the expected median AFP will be lower (36) (Figure 25-2).

Serum screening for NTDs using MSAFP is usually not effective until after 14 weeks of gestation (37). The widest separation of MSAFP values between affected and unaffected pregnancies occurs at 17 weeks (35). MSAFP screening performance is acceptable over the broader range of 15–20 weeks typically utilized in screening programs for aneuploidy. Serum marker levels can be affected

**FIGURE 25-1** Mean concentrations of AFP in maternal serum, amniotic fluid, and fetal serum at various stages of pregnancy. From Haddow, J. E. *Prenatal Screening for Open Neural Tube Defects, Down's Syndrome, and Other Major Fetal Disorders*. Semin. Perinatol. 1990, 14, 488–503, with permission.

**FIGURE 25-2** Distribution of maternal serum AFP (in MoM) in anencephalic, open spina bifida, and unaffected pregnancies.

by multiple factors, including maternal weight, ethnicity, and the presence of insulin-dependent diabetes (38). All fetuses produce AFP at a fairly constant rate determined by the size and age of the fetus and placenta. AFP entering the maternal circulation is then diluted in the intravascular space, and so the concentration is lower in larger women because of a greater volume of distribution and higher in thin women, who have a smaller volume of distribution (39). Concentrations, therefore, must be corrected for maternal weight for the most accurate evaluation. For uncertain reasons, race also affects maternal serum AFP levels. African-American women have AFP concentrations 10–15% higher than white women (38). Most screening programs typically employ race-specific AFP medians. Insulin-dependent diabetes mellitus is associated with a 20% reduction in maternal serum AFP levels, and hence, adjustment is also required for accurate interpretation of AFP levels in diabetic women (40,41).

Multiple gestations pose a diagnostic dilemma in serum screening for NTDs. In general, serum biomarkers, including AFP, in twin pregnancies are approximately twice those of singletons (42,43). Detection rates of NTDs are significantly lower in twins than in singletons. In a series of 46 twin pregnancies, using a cutoff of 5.0 MoM, the detection rate of anencephaly was 83% and open spina bifida was only 39% with a false-positive rate of 3.3% (42). Lower cutoffs, such as 3.0–3.5 MoM, provided higher detection rates (96–98% for anencephaly and 69–80% for open spina bifida) but were associated with a 12–19% false-positive rate. Given the evolution in ultrasound and its importance in the evaluation of screen-positive pregnancies as opposed to amniocentesis, utilization of lower cutoffs may be warranted in order to preserve sensitivity.

**25.2.4.3 Prenatal Screening and Diagnosis of NTDs by Ultrasound.** In addition to the important role that ultrasound plays in accurate dating and appropriate interpretation of amniotic fluid and maternal serum AFP levels, ultrasound screening for major fetal anomalies in the second trimester has become a routine part of prenatal care in many countries (44). Detailed evaluation of most fetal anatomy is best accomplished at 18–20 weeks of gestation as major anomalies can be diagnosed and time allowed for the option of pregnancy termination. While many anomalies can be visualized earlier, this time also allows for better evaluation of the cardiac anatomy than possible at earlier gestational ages. The detection rates of NTDs by ultrasound vary considerably with the quality of the equipment, the fetal position, the maternal habitus and the experience of the operator. In expert hands, ultrasonography alone has 97% sensitivity and 100% specificity in the detection of NTDs (45).

Anencephaly results from failed closure of the cephalic portion of the neural tube and disrupted cranial development resulting in exencephaly, the precursor of anencephaly. Ultrasound findings include decreased crown-rump length (CRL), absent calvaria, extruding lobulated cerebral tissue (exencephaly) or absent neural tissue, abnormal

head shape with the eyes delineating the upper portion of the fetal face in the coronal plane, and, later in gestation, polyhydramnios due to impaired fetal swallowing (Figure 25-3) (46). Given the marked abnormalities evident on ultrasound, the detection rates for anencephaly approach 100% (47). As ossification of the skull is not visualized until after 12 weeks of gestation, care should be taken in diagnosing anencephaly before this time. The abnormal contour of the head and amorphous appearing cerebral tissue are often visible in the first trimester.

Open spina bifida is detected by both cranial and spinal abnormalities on ultrasound. The two major cranial anomalies, the so-called “lemon” and “banana” signs, are typically easily recognized (48). The lemon sign describes the flattening or concavity of the frontal bones of the skull visible in the transverse plane (Figure 25-4). Decreased intraspinal pressure with concomitant downward displacement of the brain and decreased intracranial pressure is thought to cause this abnormality (49). This theory is supported by the fact that the lemon sign is visible in 98% of fetuses with open spina bifida before 24 weeks but in only 13% after 24 weeks when ossification of the cranium has progressed (50). The banana sign

**FIGURE 25-3** (A) Sagittal and (B) coronal ultrasound images of a mid-trimester fetus with anencephaly. Note the absence of the cranium above the level of the orbits and the presence of only amorphous cerebral tissue.

signifies the caudal displacement of the cerebellum with alignment of the cerebellar hemispheres as part of type II Arnold–Chiari malformation (Figure 25-4). In contrast to the lemon sign, this abnormality persists throughout gestation although visualization with ultrasound becomes more difficult in the third trimester (46).

Approximately 99% of fetuses with open spina bifida lesions exhibit at least one cranial finding on ultrasound (51). Both lemon and banana (or absent cerebellum) signs were observed in 97% of fetuses with spina bifida, ventriculomegaly in 75%, cisterna magna obliteration in 68%, and diminished biparietal diameter in 61% of fetuses. These findings, including an effaced cisterna magna, a small posterior fossa, and a small cerebellum, are strongly (>90%) associated with spina bifida (52). This study found that ventriculomegaly and the lemon sign were less frequently (81% and 53%, respectively) associated with spina bifida. As nearly all fetuses with closed spina bifida will have normal cranial anatomy, this can be used to differentiate between open and closed lesions (53).

Sonographic identification of the area of spinal dysraphism is often more difficult than detecting cranial abnormalities in spina bifida. The length of the spine must be examined in the axial, coronal, and sagittal planes (46). The axial view is most useful for visualization of all three ossification centers and will show splaying of the posterior lamina in fetuses with spina bifida (54). If the protruding sac can be visualized, the thickness of the sac wall may indicate if the defect is open or closed (54). Additionally, the approximate level of the lesion can be identified, which can provide some prognostic data regarding future neurological function (55). Three-dimensional ultrasound has garnered recent attention as an adjuvant imaging tool for fetal anatomy (56,57). This is a particularly useful tool in imaging the

fetal spine as its entirety cannot be visualized in a single plane. Furthermore, three-dimensional ultrasound is less dependent on the technical skills of the operator and may uncover spinal anomalies that would otherwise go unrecognized (58).

Recent studies have examined first-trimester sonographic markers of spina bifida. At 11–13 weeks, the nasal bone is visualized and the nuchal translucency (NT) is measured to evaluate for aneuploidy (see Section 25.3.9.5). In the same midsagittal view, the fourth cerebral ventricle can be visualized as an intracranial translucency. Preliminary studies indicate that absence of intracranial translucency is a specific marker of spina bifida (59,60) but this screen is only 50% sensitive for the anomaly (60). This has not been evaluated in large-scale trials.

**25.2.4.4 Prenatal Diagnosis of NTDs by Amniotic Fluid Biochemistry.** Traditionally, women with elevated MSAFP levels were further evaluated by amniocentesis, so that amniotic fluid levels of AFP and acetylcholinesterase were measured to confirm the diagnosis of an NTD. In a large study of nearly 10,000 women, elevated amniotic fluid acetylcholinesterase, defined as an amniotic fluid AFP concentration >2.0 MoM for the gestational age, detected 100% of anencephaly and spina bifida cases, with a false-positive rate of only 0.08% (61). The additional advantage of this approach is that the fetal karyotype can be determined from the same amniocentesis sample. As previously noted, ultrasound technology has advanced significantly since the introduction of MSAFP screening and carries detection rates for NTDs comparable to amniocentesis. Additionally, amniocentesis is an invasive procedure and is associated with a risk of pregnancy loss of 1 in 200 (6).

## 25.3 ANEUPLOIDY

### 25.3.1 Classification, Frequency, and Occurrence

Studies in the 1970s showed that chromosomal abnormalities affect approximately 1 in 160 live births (62). A more recent European study of second-trimester amniocenteses suggests that this incidence may be higher when minor alterations, such as mosaicism, are included (63). The majority of abnormalities are sex chromosome alterations or autosomal trisomies, most frequently trisomy 21, 18, or 13. Approximately 1 in 800 children is born with trisomy 21 (Down syndrome), 1 in 6000 is born with trisomy 18 (Edwards syndrome), and 1 in 10,000 is born with trisomy 13 (Patau syndrome) (64). Most autosomal trisomies are caused by nondisjunction during maternal meiosis, a process that is more frequent with advancing maternal age (see Section 25.3.2).

There are limited preventative measures that have been shown to decrease the risk of aneuploidy in pregnancy. First, conception at a younger age is associated with a decreased rate of chromosomal aberrations. Second, couples with

**FIGURE 25-4** Axial view of fetal head demonstrating findings associated with a neural tube defect. The normal contour of the articulation of the frontal bones is altered so that there is an overlap and scalloping to generate the “lemon sign.” In the posterior fossa, the cerebellum is inferiorly displaced and elongated consistent with a Type II Arnold–Chiari malformation giving the appearance of the “banana sign.”

known genetic abnormalities, including balanced translocations, may utilize preimplantation genetic diagnosis to select for unaffected embryos. While some studies have suggested that folate supplementation may decrease the risk of Down syndrome (65), others have shown no effect (66).

### 25.3.2 Maternal Age Risks

The association between advanced maternal age and an increased risk of Down syndrome was first described in the 1930s (67). A multitude of subsequent studies have confirmed this association and defined its magnitude. The risk of Down syndrome and other aneuploidies increases with maternal age, so that a 40-year-old woman has a more than 13-fold higher risk of having a pregnancy affected by Down syndrome than does a 20-year-old woman (68).

The molecular basis for the association between maternal age and aneuploidy is an increased rate of meiotic non-disjunction in aging oocytes (69). Oocytes are suspended in the dictyotene stage of prophase I from the time they are formed during fetal development until they are fertilized in adulthood. During this protracted time in prophase, the chromosomes are kept aligned on the equatorial plate by chiasmata, the sites of recombination. In the majority of cases of maternal non-disjunction it is thought that aging causes deterioration of the chiasmata and subsequent misalignment of sister chromatids. This results in missegregation of chromosome pairs to the daughter oocytes (69).

### 25.3.3 Spontaneous Fetal Loss

Pregnancies affected by aneuploidy have a greater risk of spontaneous abortion than unaffected pregnancies. True estimates of this rate are difficult to ascertain as a proportion of affected pregnancies that are detected by prenatal screening programs will be terminated and some may occur so early in development that the woman does not recognize them as a pregnancy loss. A large-scale study showed that 43% of pregnancies with Down syndrome detected by the first-trimester CVS and 23% of pregnancies with Down syndrome detected by the second-trimester amniocenteses will end in miscarriage or stillbirth (70). Fetal loss rates in pregnancies affected by trisomy 13 or 18 are even higher. Forty-nine percentage of pregnancies diagnosed with trisomy 13 in the first trimester and 42% diagnosed with trisomy 13 in the second trimester will end in miscarriage or stillbirth. Seventy-two percentage of pregnancies diagnosed with trisomy 18 in the first trimester and 65% of pregnancies diagnosed with trisomy 18 in the second-trimester will end in miscarriage or stillbirth (71). This information is vital for counseling women regarding prognoses for their affected pregnancies.

### 25.3.4 Previous Affected Pregnancy

Women with a prior pregnancy with aneuploidy carry a significant risk of recurrence in subsequent pregnancies.

For Down syndrome, the relative risk of recurrence among all women is approximately 2 (72,73). The risk is higher in women who carry the first affected pregnancy before age 35 with a relative risk of 3.5 (73). The risk of recurrence for trisomy 18 is over 3, whereas the relative risk of recurrence for trisomy 13 is the highest at over 9 (73). Again, these risks are higher in women who are under age 35 during their first affected pregnancy. Women with any offspring with trisomy are at increased risk for a different trisomy in a subsequent pregnancy (72,73). These recurrences can be explained by possible gonadal mosaicism, in cases of the homotrisonomy recurrence, or by increased rates of meiotic error in women with homo- or heterotrisonomy recurrences. These numbers may be used to alter the *a priori* risk when counseling women with a prior affected pregnancy and allow better risk estimation than the traditional 1% risk estimate provided to most women after a prior trisomic conception.

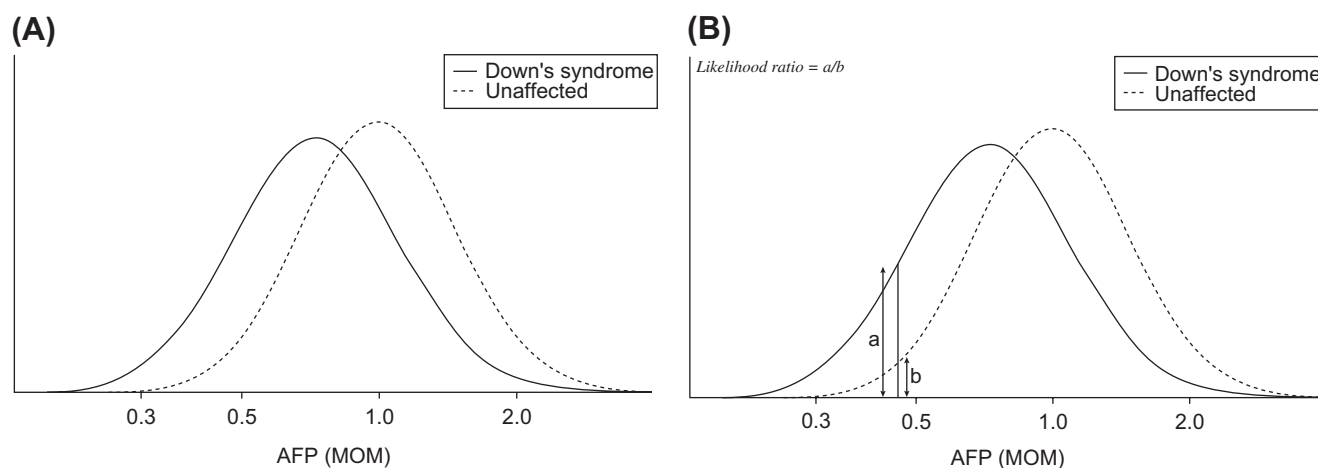

### 25.3.5 Prenatal Screening for Aneuploidy

**25.3.5.1 Maternal Age Screening.** In the early years of prenatal screening, maternal age was primarily used to select pregnancies at high risk for aneuploidy. Diagnostic testing, by amniocentesis or CVS, was offered to all women over a specific age cutoff, typically age 35. Age 35 was chosen as a cutoff as this represented the age at which the risk of Down syndrome equaled the risk of procedure-related pregnancy loss (74). Evidence has emerged that maternal age is not adequate to screen for aneuploidy. The majority of pregnancies affected by aneuploidy occur in women under 35. The American College of Obstetricians and Gynecologists (ACOG) recommends offering prenatal screening for aneuploidy to women of all ages (75). ACOG further recommends that all women should have the option to undergo invasive testing with either CVS or amniocentesis, irrespective of screening results, for chromosomal abnormalities (75).

**25.3.5.2 Second-Trimester Biochemical Screening for Aneuploidy.** Before the mid-1980s, the only options available for prenatal screening were the invasive procedures—CVS or amniocentesis. At this time, Merkatz and colleagues discovered the association between low MSAFP and trisomy 21 (76). Cuckle and colleagues confirmed this finding (77). As there is a considerable overlap between AFP levels in unaffected and affected pregnancies, a Gaussian model (Figure 25-5) was proposed to estimate the probability that an AFP level is correlated to an affected pregnancy (77).

As noted previously, AFP levels vary with gestational age. Therefore, precise estimation of gestational age is a prerequisite for valid screening with MSAFP and other serum markers and these analyte levels are expressed as MoM. A likelihood ratio for AFP, or any other serum marker, may be calculated by dividing the height of the affected pregnancy frequency distribution curve at a given MoM value by the height of the distribution

**FIGURE 25-5** (A) Distribution of maternal serum AFP (in MoM) in unaffected and Down syndrome pregnancies. (B) Estimation of the likelihood of an affected pregnancy associated with a specific AFP level.

curve of unaffected pregnancies at the same MoM (Figure 25-5b). This likelihood ratio can then be multiplied by the age-specific risk to estimate the adjusted risk. For example, a 30-year-old woman with an *a priori* age-related risk of Down syndrome of 1 in 415 and a likelihood ratio of 2.0 derived from serum screening would have an adjusted risk of 1 in 207. As the detection rate of MSAFP screening for Down syndrome and other aneuploidy is relatively low (77), expanded screening strategies, as described in the following sections, have been developed to increase detection and decrease false positives.

### 25.3.6 Serum Markers in Aneuploid Pregnancies in the Second Trimester

**25.3.6.1 Trisomy 21.** Soon after the association between low MSAFP levels and Down syndrome was discovered, Bogart and colleagues showed that high serum human chorionic gonadotropin (hCG) levels correlated with aneuploid fetuses (78,79). While several studies indicate a higher detection rate for Down syndrome when measuring the free b-subunit of hCG as compared to the intact dimeric hCG (80–83), other studies have showed no difference in the two assays (84,85). As the free b-subunit is unstable at ambient temperatures (86–89), most prenatal screening programs measure the intact hCG in the second trimester.

Unconjugated estriol (uE<sub>3</sub>), a steroid hormone derivative of dehydroepiandrosterone produced by trophoblasts, emerged next as an additional marker in the second-trimester screening. Canick and colleagues showed that uE<sub>3</sub> levels were reduced by 20% in pregnancies affected by Down syndrome (90). Initial studies showed that the combination of uE<sub>3</sub>, MSAFP, hCG (the so-called “triple screen”) and maternal age resulted in a detection rate of nearly 60% and the false-positive rate of about 3–5% for Down syndrome (91–93). Later, larger studies demonstrated detection rates of greater

than 75% with similar false-positive rates (94–96). The test is even more sensitive in women over 35, with studies indicating a 75–94% detection rate, depending on the defined cutoff (96–98).

Dimeric inhibin A (InhA) was the fourth marker added to the second-trimester serum screen, the modern version of which is now referred to as the “quadruple screen.” Multiple investigators have found elevated levels of InhA in pregnancies with Down syndrome (99–102). Subsequent studies showed that incorporation of InhA into two- or three-biomarker screening panels increased Down syndrome detection rate by 15–20% while maintaining a similar screen-positive rate (103–107). In contrast, a recent California-wide study of over 550,000 women showed that the detection rates for Down syndrome were similar between the triple screen and quadruple screen (77.4% vs 75.7%) but the screen-positive rate was 5.4% for the triple screen and just 3.8% for the quadruple screen (108). Most studies indicate that addition of InhA improves the performance of mid-trimester serum screening.

**25.3.6.2 Trisomy 18.** The discovery that all three analytes—AFP, hCG, and uE<sub>3</sub>—are decreased in pregnancies affected by trisomy 18 led to the development of screening algorithms with initial detection rates 58–80% and false-positive rates of just 0.3–0.6% (109,110). Other studies have indicated higher detection rates of over 80% with these three analytes, with similar low false-positive rates (96,111–113). Of the three biomarkers, reduced uE<sub>3</sub> levels are most predictive of trisomy 18 (114). InhA levels are also reduced in pregnancies with trisomy 18 although inclusion of InhA in the algorithm for trisomy 18 detection has not been as well studied (103,115,116). One study reported that the quadruple screen achieved a detection rate of 100% with a false-positive rate of 0.3% for detection of trisomy 18 (117).

**25.3.6.3 Trisomy 13.** Second-trimester biomarker screening is largely unsuccessful in detecting cases of trisomy 13 as there is no specific analyte pattern associated with this condition (98,117–119). Examination of

the analytes separately showed significantly lower levels of  $uE_3$  in pregnancies with trisomy 13 (119). Reduced levels of second-trimester pregnancy-associated plasma protein-A (PAPP-A) are found in pregnancies affected by trisomy 13 (120); however, this finding is of little clinical utility as PAPP-A is typically used as a first-trimester biomarker (see Section 25.3.7). Several small studies have suggested that InhA may be useful in screening for trisomy 13, but data are conflicting and limited by small sample sizes (113,116,121,122). Additionally, trisomy 13 may be detected by elevated AFP as many, but fewer than 50% (123), affected fetuses have open NTDs or ventral wall defects. Fortunately, careful ultrasound examination can identify most fetuses suspected of having trisomy 13.

**25.3.6.4 Sex Chromosome Aneuploidies.** Pregnancies affected by Turner syndrome (45,X) have significantly decreased levels of  $uE_3$  (124). Subsequent studies confirmed this observation and also showed an increase in AFP in many affected pregnancies (125). Furthermore, hCG levels are increased in pregnancies with hydropic Turner syndrome fetuses and decreased in pregnancies with nonhydropic fetuses (124). InhA is also elevated in Turner syndrome cases with hydrops and decreased in cases without hydrops (115,126).

**25.3.6.5 Triploidy.** Triploidy is defined as presence of three full sets of chromosomes. The additional set of chromosomes may be maternally derived (digynic) or paternally derived (diandric). Diandric triploid gestations typically have normal fetal growth, although there may be gross fetal malformations, and placentomegaly with partial molar changes. Digynic triploid pregnancies usually display significant fetal growth restriction and relatively small placentas. Triploidy can be incidentally detected with algorithms designed to detect Down syndrome or trisomy 18 (127,128). Depending on the parental origin of the additional set of chromosomes, second-trimester hCG may be high or low. Presumed diandric triploid pregnancies with partial molar changes are associated with high hCG levels, whereas presumed triploid digynic pregnancies are associated with low hCG levels (127). Similarly, diandric triploid gestations have high AFP levels and digynic pregnancies have normal AFP levels (129).

### 25.3.7 Serum Markers in Aneuploid Pregnancies in the First Trimester

Serum screening during the second trimester results in diagnosis of aneuploidy later in gestation, at a time when the mother may feel fetal movements, others may be aware of the pregnancy, and pregnancy termination may be more emotionally difficult for the family. Therefore, investigation has focused on earlier screening and diagnosis during the first trimester, when termination may be safer and less risky for the mother and her family.

**25.3.7.1 Trisomy 21.** Similar to the second trimester, hCG levels are elevated in the first trimester in pregnancies with Down syndrome (130,131). The detection rate

for trisomy 21 of hCG alone at a false-positive rate of 5% is 42–46% (132,133). To enhance the performance of the test, other markers were explored. Brambati and colleagues were the first to demonstrate that pregnancies affected by aneuploidy were associated with decreased levels of PAPP-A (134). This was confirmed in subsequent studies (135–139). In combination with maternal age, hCG and PAPP-A have a detection rate of approximately 67% (133). When these markers are combined with sonographically measured fetal NT (see Section 25.3.9.2.1) detection rates are even higher.

**25.3.7.2 Trisomy 18.** First-trimester maternal serum hCG and PAPP-A are decreased in pregnancies affected by trisomy 18 (136,140–142). When combined with NT, detection rates approach 90% with a false-positive rate of 1% (142).

**25.3.7.3 Trisomy 13.** Pregnancies with trisomy 13 are also associated with reduced serum levels of hCG and PAPP-A in the first trimester. Biochemical screening and NT measurement results in a detection rate of 90% with a false-positive rate of 0.5% (143).

**25.3.7.4 Sex Chromosome Aneuploidies.** A series of 46 cases of Turner syndrome showed significantly lower levels of PAPP-A and unchanged levels of hCG (144). Other sex chromosome abnormalities, such as 47XXX, XXY, XYY, were not associated with significant differences in PAPP-A or hCG levels (144).

**25.3.7.5 Triploidy.** In diandric triploidy, first-trimester maternal serum hCG is markedly increased and PAPP-A is slightly decreased. Digynic triploid pregnancies are associated with significantly reduced levels of both hCG and PAPP-A (145).

### 25.3.8 Maternal and Pregnancy Variables

**25.3.8.1 Gestational Age.** As several biomarkers vary significantly during gestation, a precise estimate of gestational age is vital for appropriate interpretation of screening results. Pregnancy dating by self-report of last menstrual period is highly variable, leading to inaccurate approximations of gestational age. Early first-trimester ultrasounds provide the most reliable dating criteria. Wald and colleagues showed that the addition of ultrasonographic measurements of fetal biometry increased the detection rate of the serum screen (including AFP, hCG, and  $uE_3$ ) by 15% for a given false-positive rate and decreased the false-positive rate by 46% at a given detection rate (146). With accurate dating, first-trimester screening is most effective between 10 and 14 weeks, and second-trimester serum screening is most effective between 15 and 22 weeks.

**25.3.8.2 Maternal Weight.** Heavier women have larger volumes of distribution and, therefore, decreased concentrations of serum biomarkers. Hence, all three analytes are adjusted based on maternal weight (39,146–148).

**25.3.8.3 Multiple Pregnancy.** As expected, hCG levels are elevated in twin pregnancies, with studies showing

free b-hCG levels approximately twice that of singleton pregnancies (149). InhA levels are also approximately doubled in twin gestations (150). In affected twin pregnancies, however, analyte levels are not consistent. The overall detection rate for aneuploidy in twin gestations is only 50–55% with second-trimester serum screening (151,152). First-trimester screening with serum biochemistry and NT measurement performs better with a detection rate of 80% and 5% false-positive rate (153), which was confirmed in prospective analyses (154,155).

Chorionicity also appears to affect first-trimester markers. Serum levels of hCG and PAPP-A are decreased in monochorionic twin gestations as compared to dichorionic gestations (156–158). By incorporating chorionicity-specific medians, the performance first-trimester screening algorithms approach that of singletons (158).

**25.3.8.4 Smoking.** In a recent study of more than 45,000 women, smoking was associated with reduced levels of first-trimester PAPP-A and hCG, reduced levels of second-trimester uE<sub>3</sub> and hCG, and increased levels of second-trimester AFP and InhA (159). These findings were in agreement with previous studies (160–170). Additionally, smoking is associated with elevated InhA (171). These altered analyte levels lead to increased screen-positive rates for Down syndrome in the second-trimester serum screen and for trisomy 18 in both the first-trimester combined and integrated tests (159).

**25.3.8.5 Ethnicity.** Several studies have demonstrated that hCG levels are higher in black women as compared to Caucasian women, but uE<sub>3</sub> levels are similar among the two groups (172). Furthermore, AFP levels are also higher in black women (173). Thus, race-specific medians have been developed for Caucasian and African-American women (174,175). These race-specific medians result in improved detection rates and lower screen-positive rates for these groups (176). A recent study showed that analyte levels also differ between Caucasian and Hispanic women resulting in lower screen-positive rates for trisomy 21 and NTDs in Hispanics (177). Ethnic-specific medians reduce this disparity (177).

**25.3.8.6 Fetal Gender.** Multiple studies have shown that pregnancies with female fetuses have reduced second-trimester AFP levels and higher hCG levels than those with male fetuses (178–185). This results in a higher false-positive rate for Down syndrome in female fetuses (185). This disparity does not result in significant differences in detection rates between the two sexes (185,186). First trimester analytes follow a similar pattern in that hCG levels are higher and PAPP-A levels are lower in women carrying female fetuses (187,188). Again, these differences result in high false-positive rates in pregnancies with female fetuses but no significant differences in detection rates (188).

**25.3.8.7 Diabetes Mellitus.** AFP levels are significantly reduced in women with pre-existing diabetes as compared to healthy controls (189,190), and this reduction

appears to be correlated with glycosylated hemoglobin, an indication of glycemic control (41). Additionally, uE<sub>3</sub> levels are slightly lower (191) and InhA levels are higher (192,193) in diabetic women. Most programs make adjustments in the standard risk calculations in diabetic women. A study examining first-trimester screening showed that women with insulin-dependent diabetes had a 15% reduction in PAPP-A, while hCG and NT measurements were unaffected (194). The authors propose that adjustments should be made to account for this difference in first-trimester screening as well.

**25.3.8.8 Renal Disease.** Women with renal disease have significantly higher levels of free b-hCG in the second trimester as compared to women with normal renal function (195). Similarly, one study found that high levels of hCG in the first trimester are correlated with potentially undiagnosed renal impairment (196).

**25.3.8.9 Medication Effects.** Numerous studies have shown that some medications may alter serum marker levels. Methadone and its metabolites inhibit the conversion of androgens to estrogens by placental aromatase (197), and methadone-addicted women have reduced uE<sub>3</sub> levels (198,199). Other opiates, such as morphine, heroin, hydromorphone, and hydrocodone, increase uE<sub>3</sub> levels (200). In a large cohort study, Pekarek and colleagues showed that multiple classes of medications, including methadone, immunosuppressants, antidepressants, antiemetics, antihypertensives, antiepileptics, and asthma medication, alter multiple serum biomarker levels (199). Further analysis showed that screen-positive rates for NTDs were higher in women taking immunosuppressants, antibiotics, and antidepressants and the screen-positive rate for trisomy 18 was higher in women taking methadone (199).

**25.3.8.10 Assisted Reproduction.** Analyte levels are altered in pregnancies conceived by assisted reproductive technologies. Second-trimester levels of InhA are increased in patients undergoing all types of assisted reproductive technologies (ART), while uE<sub>3</sub>, hCG, and AFP are altered only in women undergoing certain treatments (201). In contrast, first-trimester analytes are not significantly altered in patients undergoing ART (202).

**25.3.8.11 Vaginal Bleeding.** Cuckle and colleagues showed in a meta-analysis of second-trimester serum screens that vaginal bleeding was associated with a 10% increase in MSAFP and no change in uE<sub>3</sub> or hCG (203). The authors speculated that if adjustments were made for vaginal bleeding, there would be <1% gain in the detection rate of Down syndrome. A retrospective study of nearly 50,000 women undergoing first-trimester screening demonstrated no difference in hCG, PAPP-A, or NT measurements in women with vaginal bleeding in early pregnancy (204).

**25.3.8.12 Other Pregnancy Complications.** False-positive second-trimester screens for Down syndrome are associated with multiple adverse outcomes including growth restriction, low birth weight, small for gestational

age, preterm delivery, preeclampsia, and stillbirth (205–207). Low second-trimester uE<sub>3</sub> is associated with fetal death, miscarriage, and anencephaly (208). Reduced uE<sub>3</sub> is also associated with several genetic syndromes, such as Meckel–Gruber syndrome, characterized by encephalocele, postaxial polydactyly, and cystic kidneys, Smith–Lemli–Opitz syndrome, a defect in cholesterol biosynthesis resulting in multiple congenital anomalies and intellectual disability, and X-linked ichthyosis, a disease with altered steroid metabolism and characteristic scaly skin (208). The utility of low estriol for the detection of Smith–Lemli–Opitz syndrome has led some screening programs to report a specific risk for this disorder and recommend diagnostic evaluation when the risk exceeds a specific threshold. Implementation of such a program increases the screen-positive rate by <0.1%. (209) Similarly, low levels of first-trimester PAPP-A are associated with a number of obstetrical complications, including fetal loss, low birth weight, preeclampsia, gestational hypertension, preterm birth, preterm premature rupture of membranes, abruption, and stillbirth (210,211). Increased NT and low levels of hCG are also correlated with increased spontaneous fetal loss (211). Consequently, patients with abnormal serum screening results and normal fetal karyotypes may warrant monitoring for subsequent adverse pregnancy outcomes.

## 25.3.9 Ultrasound Screening for Fetal Chromosome Abnormalities

### 25.3.9.1 Ultrasound Screening in the Second Trimester.

**25.3.9.1.1 Nuchal Fold.** In the 1980s, mid-trimester thickening of the nuchal fold was first described as sonographic marker of Down syndrome. (212) Using a cutoff of 6 mm or greater for the nuchal fold has been demonstrated to allow detection of approximately 40% of fetuses with trisomy 21 (213,214) while the finding of a nuchal fold of <6 mm reduces the risk of Down syndrome to <1% (215). As an isolated marker, a thickened nuchal fold has a likelihood ratio of 9.8 for trisomy 21 (216).

**25.3.9.1.2 Femur and Humerus.** The second sonographic marker of Down syndrome that emerged was a relatively short femur length (217). The ratio of the femur length to the biparietal diameter is used to detect the relatively shortened femurs (218,219). The combination of a thickened nuchal fold and relatively short femur demonstrated a sensitivity of 75% and specificity of 98% (220). A short humerus appears to be a more sensitive and specific marker for Down syndrome (221). When combined with nuchal fold thickness, the sensitivity of a short humerus was 75% (222). Multiple subsequent studies have confirmed this association and showed a marked increase in the risk of Down syndrome when both humerus and femur length were short (223–226).

**25.3.9.1.3 Pyelectasis.** Although there is a high prevalence in euploid fetuses, pyelectasis or renal pelvic

dilation occurs more commonly in fetuses with trisomy 21 (227). Up to 25% of fetuses with Down syndrome have this minor abnormality, whereas only 2–3% of euploid fetuses demonstrate this finding (227–231). Despite this disparity in prevalence, however, when noted as an isolated finding, renal pelvic dilation is not associated with an increased likelihood of aneuploidy (216).

**25.3.9.1.4 Intracardiac Echogenic Foci.** The pathology literature previously reported an increased incidence of calcifications in the papillary muscle of infants with Down syndrome (232). Subsequent studies showed that an intraventricular echogenic focus (Figure 25-6) was associated with Down syndrome (233–235). Although this association has been confirmed in multiple studies (236–238), its clinical significance in isolation remains controversial and the likelihood ratio associated with this finding is 1.1 (216). Several studies have noted an increase in the frequency of this finding in certain racial groups (239). This finding, as well as advances in ultrasound technology, have enabled better visualization and have likely contributed to the poor specificity of this marker for aneuploidy.

**25.3.9.1.5 Choroid Plexus Cysts.** Choroid plexus cysts (Figure 25-7) are also associated with aneuploidy, especially trisomy 18 (240,241). Approximately 50% of fetuses with trisomy 18 will have a choroid plexus cyst (242). However, only 1% of fetuses with isolated choroid plexus cysts will have aneuploidy (242).

**25.3.9.1.6 Combined Markers.** Given the high proportion of fetuses with isolated sonographic markers of aneuploidy that have a normal karyotype, multiple scoring systems have been developed to quantify the risk of aneuploidy with a combination of markers (243,244). By integrating maternal age into the scoring system, further refinement of the method can be used for patient counseling to modify the *a priori* risk of aneuploidy (245,246).

**FIGURE 25-6** Four chamber view of the fetal heart. Note bright, echogenic focus in the left (posterior) ventricle which represents calcium deposition at the point of attachment of the chordae tendinae to the papillary muscle.

The combination of more than one sonographic marker is associated with over a 5-fold increase in the risk of Down syndrome, whereas a normal ultrasound decreases the chance of Down syndrome by approximately one-half (247).

**25.3.9.2 Ultrasound Screening in the First Trimester.** With improvements in ultrasound imaging technology and increased interest in earlier prenatal diagnosis, there have been significant advances in first-trimester ultrasound for aneuploidy screening such that first-trimester genetic sonograms are valuable adjuncts to biochemical analysis in prenatal screening.

**25.3.9.2.1 Nuchal Translucency.** NT is the first-trimester analog of the second-trimester nuchal fold (Figure 25-8). NT is the term used to describe a collection of fluid behind the fetal neck recognized during the first trimester (248). While all fetuses have some degree of measurable NT, fetuses with trisomy 21, as well as other chromosome abnormalities, have measurements that are two- to three-fold larger than that of unaffected fetuses (248), making it a powerful marker for estimation of the risk of fetal aneuploidy. In addition to its role in aneuploidy screening, an increased NT

has also been identified in a multitude of single-gene disorders and structural malformations (e.g. congenital cardiac defects, renal malformations, neuromuscular abnormalities) (249,250). For this reason, any fetus with an NT  $\geq 3$ –3.5 mm should have a targeted ultrasound evaluation for careful assessment of anatomy.

The optimal time measure in the NT is between 11 and 13 6/7 weeks, at a corresponding CRL of 45–84 mm (131). The NT should be measured in the sagittal plane at its maximal thickness. The NT measurement may be expressed in multiple ways. One way is to report the measurement is the delta NT, which is the difference in millimeters between the normal median for the CRL and the measured NT (251). The second approach is to derive the MoM by dividing the measured NT by the normal median at the gestational age (252). This allows for an age-adjusted risk assessment similar to biochemical screening. The third method, termed *the mixture model*, involves analyzing the NT in a CRL-dependent and CRL-independent manner as a higher proportion of aneuploid fetuses have CRL-independent increases in NT (253). Regardless of the analysis methodology, several prospective studies have shown that detection rates for Down syndrome and other aneuploidies approach 80% with NT measurement (131,254).

Multiple studies have shown that increased NT is associated with aneuploidy (251,255–257). Using an increased NT as the sole criteria for fetal aneuploidy screening detects approximately 70–75% of fetuses with trisomy 21, and when combined with the maternal age-associated *a priori* risk, a detection rate in excess of 80% is achievable (254,258–261).

Fetal NT measurements are independent of maternal serum levels of hCG and PAPP-A; therefore, these markers can be combined into a single screening test. The combination of free  $\beta$ -hCG or hCG, PAPP-A, and NT with maternal age is able to detect approximately 80–85% of fetuses with trisomy 21 at a false-positive rate of 5% (262–269).

**25.3.9.2.2 Fetal Heart Rate.** Studies of fetal heart rate (FHR) in association with aneuploidy have reported conflicting results. Aneuploidy has been associated with both bradycardia and tachycardia (270–272). While some studies have shown significant gains in detection rates by adding FHR to other first-trimester markers (270), other studies have suggested negligible effects on detection rate (272).

**25.3.9.2.3 Ductus Venosus.** A significant proportion of fetuses with chromosomal aberrations will have abnormal high-impedance flow through the ductus venosus due to structural or functional cardiac abnormalities (273,274). Analysis of pooled data from previous studies showed that while only 5% of karyotypically normal fetuses will display abnormal ductus flow, approximately 70–90% of fetuses with trisomy 21, 28, 13 or Turner syndrome will have this finding (275). Addition of ductus flow to a combined screening

**FIGURE 25-7** Axial views of the fetal head demonstrating the presence of hypoechoogenic areas within the lateral ventricle consistent with a diagnosis of choroid plexus cysts. (A) Unilateral choroid plexus cyst. (B) Large bilateral choroid plexus cysts in a fetus that proved to have trisomy 18.

**FIGURE 25-8** Nuchal translucency measurement in the first trimester. NT within average range: (A) fetal prone position and (B) Fetal supine position. Increased NT: (C) prone and (D) supine.

included maternal age, NT, FHR, hCG, and PAPP-A resulted in a detection of 96%, 92%, 100%, and 100% of trisomy 21, 18, 13, and Turner syndrome, respectively (275). Abnormal ductus flow in twin pregnancies was also associated with an increased rate of aneuploidy or other adverse outcomes, such as twin-twin transfusion syndrome, but 75% of dichorionic and 40% of monochorionic twins with this finding had normal outcomes (276). Furthermore, recent study showed that an altogether absent ductus venosus is associated with aneuploidy or other genetic syndromes in a high proportion of cases when the NT is increased, whereas this abnormality is associated with a favorable prognosis in the setting of a normal NT (277).

**25.3.9.2.4 Tricuspid Regurgitation.** Tricuspid regurgitation, detected by pulsed wave Doppler flow, has been associated with Down syndrome (278,279). This finding is believed to be associated with the high incidence of valvular structural abnormalities in the setting of aneuploidy and/or the decreased cardiac compliance associated with myocardial dysfunction. By adding tricuspid regurgitation assessment to a program based on maternal age, NT, FHR, hCG, and PAPP-A, Down syndrome detection rose from 91% to 96% (280).

**25.3.9.2.5 Nasal Bone.** A high proportion of aneuploidy fetuses demonstrate hypoplasia or failure to visualize the nasal bone in the first trimester (Figure 25-9). Interrogation of the fetal facial profile in the first trimester is an extension of the physical examination performed in the neonatal period, in which a flattened nasal bridge and profile are often noted in aneuploidy infants, especially those with trisomy 21 (281). Although dependent

somewhat on ethnicity, up to 75% of fetuses with trisomy 21 will have nonvisualization of the nasal bone in the first trimester compared to fewer than 1% of euploid fetuses (281,282). By adding the nasal bone to other first-trimester screening, including hCG, PAPP-A, NT, and FHR, this strategy decreased the false-positive rate for trisomy 13, 18, 21, and Turner syndrome and further increased the detection rate for trisomy 21 (282,283).

## 25.3.10 Integrated Screening

The implementation of first-trimester programs has shifted the paradigm of prenatal screening and diagnosis. By combining ultrasound with biochemical analysis, high detection rates with low false-positive rates can be achieved. In the largest study of first-trimester screening of over 8500 patients, a screening program based on maternal age, serum hCG and PAPP-A levels, and NT measurement showed a 79% detection rate for Down syndrome with a false-positive rate of 5% (284). These rates are comparable with second-trimester biochemical screening, as shown in the Serum, Urine and Ultrasound Screening Study (SURUSS) (267). SURUSS indicated that using a fully integrated screening program, combining NT, first-trimester PAPP-A, and second-trimester AFP, uE3, hCG, and InhA, provides a low false-positive rate at 1.2% with an 85% detection rate (285). The First- and Second-Trimester Evaluation of Risk (FASTER) trial was a landmark prospective study of nearly 40,000 women that compared multiple combinations of screening strategies, including sequential (first- and second-trimester results reported independently) vs integrated

**FIGURE 25-9** Middle sagittal image of fetus in supine position for assessment of fetal nasal bone. (A) Nasal bone present—note the echogenic area (arrow) below the skin echo to give appearance of an equal sign. (B) Absent nasal bone.

(first- and second-trimester results reported as single risk assessment) screening (269). FASTER sequential screening resulted in a 95% detection rate and fully integrated screening resulted in a 96% detection rate. However, sequential screening results in higher false-positive rates, possibly resulting in unnecessary invasive diagnostic tests (269,286).

Despite its high detection rates and low false-positive rates, exclusive use of integrated screening eliminates the option of first-trimester risk assessment and early prenatal diagnosis. Hybrid screening models are often employed in clinical practice. One model is contingent sequential screening in which first-trimester results are used to triage patients to have no further screening, proceed with second-trimester screening, or undergo an immediate CVS. This model has not been evaluated prospectively, but decision analysis modeling has shown that this is the most cost-effective approach (287,288). Using the stepwise sequential model, a preliminary risk may be quoted in the first trimester for women at highest risk. This provides the option of immediate CVS or awaiting the fully integrated screening results during the second trimester while minimizing the chance of additive false-positive results (75).

### 25.3.11 Frontiers in Prenatal Screening and Diagnosis

While significant efforts have focused on improving the sensitivity and specificity for serum and ultrasound techniques for prenatal screening, definitive diagnosis still requires an invasive procedure such as CVS or amniocentesis. Noninvasive techniques for obtaining fetal genetic material are the newest developments in prenatal screening and diagnosis (289).

Early in pregnancy, small erosions in the decidua capsularis allow trophoblast cells enter the uterine cavity and shed into the cervix. In 1971, Shettles and colleagues first reported retrieval of trophoblasts from the endocervix in the first trimester for sex determination (290). Later studies showed that these cells could be obtained for aneuploidy screening by FISH and hemoglobin genotyping (291–293). Depending on the exact retrieval technique, success rates vary widely from 40% to 90% (294); thus, further studies are required to optimize this potentially valuable noninvasive method.

The presence of fetal cells in the maternal circulation has been known for over a century. As the concentration is very low, at approximately 1 per 10 million (295), the development of efficient isolation and analysis techniques remain challenging. A multicenter trial using this technique showed that the correct fetal gender was detected in <50% of cases (296). More refined techniques have been investigated (297,298) but this methodology remains experimental.

The most promising technique involves isolation of cell-free fetal nucleic acids. In 1997, Lo and colleagues showed that fetal DNA could be amplified from maternal blood (299). The cell-free fraction of blood likely represents a better source as the concentration of fetal DNA is nearly 1000-fold higher in plasma than in the cellular component (300). However, fetal DNA still represents a low (3–6%) proportion of the total circulating free DNA (300), making detection of alterations in fetal chromosome dosage still challenging. One answer to this problem is use of massively parallel genomic sequencing, a type of shot-gun sequencing in which short tags across the genome are amplified, sequenced, and quantified (301,302). Evaluation of over 700 pregnancies with this technique demonstrated a 100% sensitivity and 98% specificity in the detection of Down syndrome (303). Studies are ongoing to assess the utility of this technology in a variety of patient populations.

## 25.4 SUMMARY

Prenatal aneuploidy screening of all women with a combination of biochemical and sonographic analysis has become standard of care in the United States, among a multitude of other countries. Advances in serum screening and ultrasound technology has improved detection rates and decreased false-positive rates, reducing the need for invasive diagnostic procedures. In particular, integrated

screening, combining first- and second-trimester serum and ultrasound analysis, has revolutionized prenatal screening with detection rates of >95% (269). Newer methodologies involving fetal nucleic acid extraction and analysis from maternal serum are currently under investigation. If proven effective, these techniques could supplant the current prenatal aneuploidy screening paradigm and make invasive procedures, such as CVS and amniocentesis, obsolete.

### 26.1 INTRODUCTION

The cornerstone of prenatal diagnosis has been the direct evaluation of fetal tissue. Advances resulting from the Human Genome Project have increased the number of fetal abnormalities amenable to invasive prenatal diagnosis. In addition, in the past few decades, there has been an expansion of our capabilities to assess risk for fetal abnormalities by noninvasive screening modalities including high-resolution ultrasonography and maternal serum analyte screening. Effective screening protocols reduce the number of invasive procedures in women carrying unaffected fetuses. Recent data showing improved safety of chorionic villus sampling (CVS) and amniocentesis now raise the possibility of offering invasive prenatal diagnosis to all women in the first and second trimesters. Indeed, the American College of Obstetricians and Gynecologists has recommended that invasive diagnostic testing for aneuploidy should be available to all women, regardless of maternal age (American College of Obstetricians and Gynecologists (2007)).

This chapter reviews the techniques used for invasive prenatal diagnosis and their safety. Recent advances in noninvasive screening protocols, including new approaches combining first-trimester ultrasonography and maternal serum analytes to provide a risk assessment for fetal Down syndrome and other aneuploidies. Recent developments in the isolation and analysis of fetal DNA from maternal blood are briefly addressed.

### 26.2 AMNIOCENTESIS

#### 26.2.1 Traditional Amniocentesis: 15 Weeks Gestation and Greater

**26.2.1.1 Technique.** Amniocentesis, the aspiration of amniotic fluid, has traditionally been performed at

and after 15–17 weeks gestation (menstrual weeks). At this stage of gestation, the volume of amniotic fluid is approximately 200 mL. The ratio of viable to nonviable cells in the amniotic fluid of second-trimester fetuses is relatively high (1), thus allowing timely culture and diagnosis of fetal cytogenetic abnormalities. This allows women the option of pregnancy termination when a fetal abnormality is detected.

Amniocentesis is routinely performed in an outpatient facility. An ultrasound examination should be done immediately before the procedure to evaluate fetal number and viability, perform fetal biometric measurements to confirm gestational age, establish placental location, and estimate amniotic fluid volume. In our center, a fetal anatomic survey to screen for major anomalies is standard at the time of amniocentesis. In addition, ultrasonography may be useful in discovering maternal anatomic conditions (e.g. uterine fibroids, overlying bowel) that could influence the performance of the amniocentesis.

Once the preoperative ultrasound examination is completed, a needle insertion site is chosen. We prefer to insert the needle as close to the midline fundal area of the uterus as is possible, but this is not always the site at which the optimal pocket of amniotic fluid is located. Not infrequently, a lower uterine segment or lateral approach is required. We seek to avoid the placenta if possible; however, transplacental amniocentesis has not been shown to reduce the safety of amniocentesis (1–3). If tapping the optimal pocket of fluid requires traversing the placenta, we select the thinnest and most peripheral portion of the placenta possible through which the needle can be directed. If a transplacental approach is selected, the umbilical cord insertion site should be identified and avoided. Maternal bowel and bladder should also be located as these should likewise be avoided. A

local subcutaneous anesthetic (e.g., 2–3 mL of 1% xylocaine) may be used, but we usually find this unnecessary as many women complain of mild discomfort when the needle traverses the parietal peritoneum of the uterus, and this cannot be anesthetized with a local agent.

After the maternal skin is cleaned with an iodine-based solution, sterile drapes are placed around the needle-insertion site to help maintain an aseptic field. We prefer a 22- or 23-gauge spinal needle and recommend no larger than a 20-gauge. It has been suggested that use of a 20-gauge needle is associated with lower risk of intrauterine bleeding in case of transplacental needle insertion for faster fluid retrieval when compared with a 22-gauge needle; however, use of a 20-gauge needle is associated with more immediate discomfort during the procedure (4). Ultrasonographic monitoring of the amniocentesis with continuous visualization of the needle should be performed throughout the procedure. Although three-dimensional (3D) and 4-dimensional real-time sonography represent a rapidly developing area of medical imaging, and they have been used recently to guide prenatal invasive procedures, these modalities do not appear to offer any advantages over 2-dimensional real-time sonography, at least as determined by reducing the number of needle insertions (5). Ultrasound gel is applied adjacent to the insertion site, and a real-time ultrasound transducer is held in position such that the ultrasound beam is directed parallel to the planned needle track. A local anesthetic (e.g., 2–3 mL of 1% xylocaine) may or may not be used; however, local anesthesia does not appear to affect the level of pain of the procedure (6,7). Neither do other techniques such as lidocaine–prilocaine cream applied to the skin (8). Counseling before amniocentesis should emphasize that the actual pain and anxiety experienced during the procedure are significantly lower than expected (9). Needle insertion should be performed with one smooth continuous motion until the needle tip is within the amniotic cavity (Figure 26-1A–C). Some practitioners locate the needle tip within the subcutaneous fat and assess the distance from tip to amniotic cavity as well as the appropriate needle angle required to successfully enter the amnion and avoid maternal structures and the fetus. Amniotic membrane “tenting” is rarely encountered in procedures after 15 weeks gestation; in such cases, resolution usually occurs when the needle is rotated upon its axis or advanced further into the cavity. If such maneuvers fail to obtain amniotic fluid, needles should not be directed away from the axis of insertion and arbitrarily moved within the cavity as such actions can lead to lacerations of the amniotic membrane. In these cases, consideration of needle removal and choosing an alternative insertion site is warranted.

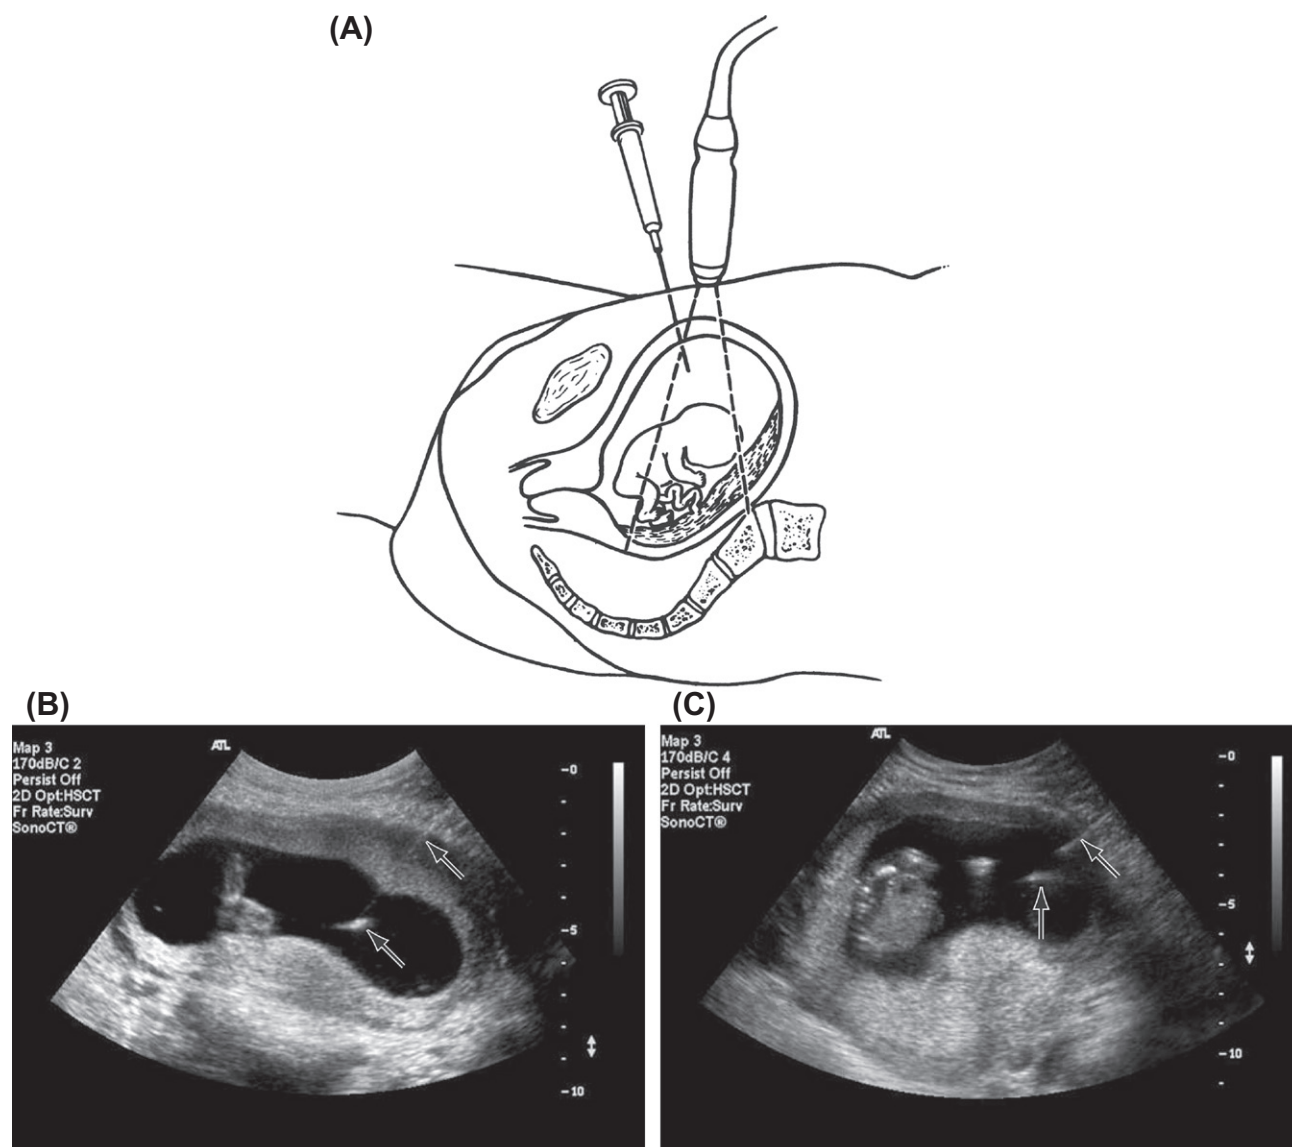

The initial 2–3 mL of amniotic fluid is aspirated into a syringe. These first few milliliters are theoretically the most likely to contain maternal cells from blood vessels, the abdominal wall, or the myometrium; therefore, this initial sample is usually discarded or set aside for

$\alpha$ -fetoprotein (AFP) analysis. For a second-trimester amniocentesis performed at 15–20 weeks inclusive, 20–30 mL of amniotic fluid is usually aspirated. Some operators recommend aspirating amniotic fluid directly into vacuum tubes, eliminating some manipulation with the needle (10,11). We do not find use of vacuum tubes to be particularly helpful. Once the amniotic fluid is obtained, the specimen is clearly labeled and transported at ambient temperature to the laboratory.

Amniotic fluid and urine are often indistinguishable in appearance. Analysis of cells derived from maternal urine could obviously lead to erroneous interpretations of fetal status. Inadvertent aspiration of maternal urine is a particular risk when a suprapubic needle insertion site is chosen. If the origin of aspirated fluid is in doubt, tests should be performed to determine its origin. Our group found that the crystalline arborization pattern characteristic of amniotic fluid is observed if the fluid is allowed to dry on an acid-cleaned slide and examined under low power (~100 magnification) (12). This test readily differentiates amniotic fluid from urine. However, with the widespread use of concurrent ultrasound, such tests should only be rarely necessary.

Bloody amniotic fluid is aspirated in perhaps 1–2% of amniocenteses. The blood, which is almost always maternal in origin, does not adversely affect amniotic cell growth. Indeed, the performance of a transplacental amniocentesis has been shown not to increase the risk for fetal loss compared to non-placental procedures but may increase the risk for a bloody tap. By contrast, brown- or dark red- or wine-colored amniotic fluid is associated with an increased likelihood of poor pregnancy outcome. This color indicates prior intra-amniotic bleeding, with hemoglobin breakdown products accounting for the fluid color. Pregnancy loss eventually may occur in about one-third of such cases (13). If the abnormally colored fluid is also characterized by an elevated AFP level, the outcome is usually unfavorable (fetal death, anencephaly, spontaneous abortion, or fetal abnormality). Green-colored amniotic fluid, presumably due to meconium staining, is apparently not associated with poor pregnancy outcome (14–16). By contrast, brown amniotic fluid has been associated with an increased risk of fetal aneuploidy (15).

The propriety of administering Rh immunoglobulin (RhIG) to prevent Rh immunization in unsensitized women with Rh-positive fetuses remains controversial. Fetomaternal transfusion by disruption of the fetoplacental circulation logically might have an immunizing effect; however, the magnitude of the risk has not been determined. The task is difficult because one must consider such variables as ABO compatibility, number of needle insertions, placental location, and the amount of fetal blood transfused into the maternal circulation. Early investigators opined that prophylactic RhIG should not be administered after genetic amniocentesis (17), but almost all now advocate its routine use (18–21). The dose to be administered is also controversial. The American

College of Obstetricians and Gynecologists recommends that 300  $\mu$ g of RhIG be administered for an exposure of 30 mL of fetal blood (22). In the United Kingdom, the recommended dose of RhIG is 50  $\mu$ g before 20 weeks gestation and 100  $\mu$ g thereafter (23). We routinely administer 300  $\mu$ g of RhIG after genetic amniocentesis, regardless of whether the needle has traversed the placenta.

Following amniocentesis, the fetal heart motion should be documented by ultrasonographic visualization. The patient is observed briefly after the procedure and is instructed to report any fluid loss or bleeding per vagina, uterine cramping, or fever. Although antibiotic prophylaxis after amniocentesis has been recommended by one group, we and others believe that the

risks outweigh the benefits (24). Reasonably normal activities may be resumed after the procedure; however, we recommend that strenuous exercise (e.g. jogging or aerobic exercises) and coitus be avoided for at least a day.

**26.2.1.2 Multiple Gestations.** In multiple gestations, amniocentesis can usually be performed on all fetuses, provided amniotic fluid volume is adequate (25). After aspiration of amniotic fluid from the first sac, 2–3 mL of indigo carmine, diluted 1:10 in bacteriostatic water, is injected before needle withdrawal. The second amniocentesis is then performed. The second needle is then inserted into the sac of the second fetus, preferably determined after visualizing the membranes separating

the two sacs. Aspiration of clear fluid confirms that the second sac has truly been entered (Figure 26-2). In experienced hands, amniocentesis is performed successfully in more than 95% of twin pregnancies with ostensibly no increased risks over that of amniocentesis in singleton pregnancies (25–27). Anderson and Goldberg (26) observed a postprocedure twin-loss rate of 3.57% up to 28 weeks, a rate interpreted as not increased over the sum

**FIGURE 26-2** Technique for amniocentesis in twin gestations. (A) Fluid is aspirated from the first amniotic sac. (B) Blue indigo carmine dye is injected into the first amniotic sac. (C) A second tap is made in the ultrasonographically determined location of the second fetus. Clear fluid confirms that the second amniotic sac was successfully aspirated. (From Elias, S.; Gerbie, A. B.; Simpson, J. L., et al. *Genetic Amniocentesis in Twin Gestations*. Am. J. Obstet. Gynecol. 1980, 138, 169, with permission.)

of background twin-loss rate plus the loss rate associated with singleton amniocentesis; a similar rate of pregnancy loss (3.87%) was reported by Toth-Pal and colleagues among women with multiple gestations undergoing amniocentesis before 24 weeks gestation (27).

Most recently, Cahill and colleagues reported a 16-year retrospective cohort of all twin pregnancies that underwent ultrasound evaluation at the Washington University School of Medicine, St. Louis, MO, who were followed for pregnancy outcomes. Women who underwent amniocentesis were compared with those who had not. Fetal loss was defined as loss before 24 weeks gestation. Of 1934 twin pregnancies, 311 women elected amniocentesis. Women who elected amniocentesis were more likely to experience a pregnancy loss than those who did not (3.2% vs 1.4%; risk difference, 1.80%; 95% CI, 0.24–3.84%, which was significant after adjustment for advanced maternal age, chorionicity, sonographic findings, alcohol exposure and race (adjusted odds ratio, 2.9; 95% CI, 1.2–6.9). Thus, the attributable risk of pregnancy loss before 24 weeks gestation after mid-trimester amniocentesis in twin pregnancies was found to be 1 in 56 (1.8%) (28).

Triplets and higher order multiple gestations can be managed similarly by sequentially injecting dye into successive sacs. As long as clear fluid is aspirated, one can be reassured that a new amniotic sac has been entered. However, the overall safety of amniocentesis in triplets and higher order multiple gestations has not yet been formally determined.

Other techniques for sampling multiple gestations have been reported, including a single-puncture technique and an “air-bubble” infusion procedure. Despite advances in ultrasonography, we have concerns that single-puncture techniques could lead to cross-contamination between sacs, resulting in diagnostic inaccuracies. In addition, we believe it is unwise to instill any substance into the amniotic cavity unless the instillation is performed in a strict, aseptic manner and serves to considerably and consistently improve safety or accuracy. More recently, some operators have not used dye instillation to distinguish separate sacs, instead relying on ultrasonographic visualization alone (29–31). In view of the considerable positive experience with dye instillation techniques over the past 25 years with regard to safety and accuracy, we still prefer the dye instillation procedure described above.

**26.2.1.3 Safety.** Any procedure that involves passing a device into an organ, especially the pregnant uterus, carries a risk. Amniocentesis is no exception. Amniocentesis carries potential danger to both mother and fetus. Maternal risks are quite low, with symptomatic amnionitis occurring only rarely. Minor maternal complications such as transient vaginal spotting and minimal amniotic fluid leakage occur in 1% or less of cases, but these are almost always self-limited in nature. Other very rare complications include intra-abdominal organic injury or hemorrhage.

The safety of traditional amniocentesis has been addressed by several large collaborative studies. The U.S.

National Institute of Child Health and Human Development (NICHD) conducted the first major prospective study of genetic amniocentesis that comprised 1040 subjects and 992 matched controls. Of the 1040 women undergoing amniocentesis, 950 (91.3%) had the procedure performed for cytogenetic analysis and 90 (8.7%) to evaluate for the possible presence of an inborn error of metabolism. Of all women who underwent amniocentesis, 3.5% experienced fetal loss between the time of the procedure and delivery compared with 3.2% of controls; the slight difference was not statistically significant and disappeared completely when corrected for maternal age. In Canada, a collaborative group conducted a cohort study but did not include a concurrent control group (32,33). Analysis was based on 1223 amniocenteses performed during 1020 pregnancies in 900 women. The pregnancy loss rate was 3.2%, a frequency similar to that reported in the U.S. collaborative study.

A later British collaborative study found that the rate of fetal loss after amniocentesis was significantly greater than in controls (2.6% vs 1%) (34). In the British study, however, one common indication for amniocentesis was elevated maternal serum  $\alpha$ -fetoprotein (MSAFP), now recognized itself as a factor associated with fetal loss and adverse perinatal outcome. Analysis after excluding subjects undergoing amniocentesis for that indication lowered the loss rates between subject and control groups to <1%, albeit still a significant difference (35).

None of the collaborative studies cited above were conducted with high-quality ultrasonography as defined by today's standards, nor was concurrent ultrasonography universally applied. More relevant data are from a more recent Danish randomized controlled study of amniocentesis that involved 4606 women aged 25–34 years who were without known risk factors for fetal genetic abnormalities (36). Women with three or more previous spontaneous abortions, diabetes mellitus, multiple gestation, uterine anomalies, or intrauterine contraceptive devices were excluded. Maternal age, social group, smoking history, number of previous induced and spontaneous abortions, stillbirths, live births, and low-birth-weight infants were comparable in the study and control groups, as was gestational age at the time of entry into the study. Amniocentesis was performed under real-time ultrasound guidance with a 20-gauge needle by experienced operators. Follow-up evaluation was available for all but three women. The spontaneous abortion rate after 16 weeks was 1.7% in amniocentesis patients compared with 0.7% in controls ( $P < 0.01$ ), with a 2.6-fold relative risk of spontaneously aborting if the placenta was traversed. Transplacental needle passage is a risk factor that has more recently been shown not to increase the risk for postprocedure loss (see previous). The frequency of postural malformations in the infants in the two groups did not differ. However, respiratory distress syndrome was diagnosed more often (relative risk 2.1) in the study group and more infants were treated for

pneumonia (relative risk 2.5). An assessment of the safety of second-trimester amniocentesis can also be found in the CEMAT study that compared conventional second-trimester amniocentesis to early amniocentesis (37). In this multicenter trial performed by experienced operators using concurrent ultrasonography, the total loss rate in the second-trimester amniocentesis cohort was 5.9%.

More recent studies evaluating the safety of amniocentesis continue to confirm the safety of the second-trimester procedure. In a study from British Columbia, Baird and colleagues (38) considered the question of whether children delivered of women who had mid-trimester amniocentesis can be identified by a population-based database of congenital anomalies and disabilities at a different rate from that of matched controls (i.e. offspring of women who had not undergone amniocentesis). The authors studied 1296 cases (651 males and 645 females) and 3704 matched controls (1867 males and 1837 females) among live births (1972–1983) from the Health Surveillance Registry with data collected to 1990 to allow a follow-up of 7–18 years. Cases were children of mothers who had mid-trimester amniocentesis for advanced maternal age (35 years or older) and whose results were normal for chromosomal disorders and neural tube defects. When possible, three controls per case were matched for age of mother, sex, date of birth, and health from provincial birth records. One hundred and twenty-eight (9.9%) of the cases and 308 (8.3%) of the controls were registered (relative risk 1.23); this relative risk was not significantly different from one. The likelihood of having disabilities was examined for cases as compared with controls, and no difference was found except for an increased ABO isoimmunization associated with amniocentesis. Overall, this study provides reassuring data for patients considering mid-trimester amniocentesis with respect to long-term outcome. Tongsong and colleagues (39) reported a large-scale cohort study among 2256 women carrying singleton pregnancies undergoing amniocentesis between 15 and 24 weeks gestation and a control group matched on a one-to-one basis for maternal age, parity, and socioeconomic status. The authors found no significant differences in fetal loss rates, premature deliveries, or placental abruptions between the two groups; however, the study was not powered to identify differences less than 1%.

Using the database from the National Institute of Child Health and Human Development-sponsored multicenter First and Second-Trimester Evaluation of Risk (FASTER) trial designed to compare first-trimester Down syndrome screening with nuchal translucency, pregnancy-associated plasma protein A (PAPP-A), and free  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG) to second-trimester screening with AFP, hCG, unconjugated estriol and inhibin A, Eddleman and colleagues analyzed the procedure-related fetal loss rate after mid-trimester amniocentesis (40). Among those enrolled in the FASTER trial, 3096 women underwent mid-trimester amniocentesis (study group) and 31,907 did not (control group). The spontaneous

fetal loss rates <24 weeks gestation were 1.0% in the amniocentesis group and 0.94% in the control group. Multiple logistic regression analysis was used to adjust for potential confounders. The difference between these two groups was not significant ( $P=0.74$ , 95% CI—0.26–0.49%). Thus, these investigations concluded that there was no significant difference in loss rates between those undergoing amniocentesis and those not undergoing this procedure. However, the safety of amniocentesis was not a primary endpoint of the FASTER trial, and the authors' interpretation of their data was controversial (41–45).

Two literature reviews corroborate the relatively low frequency of pregnancy loss after second-trimester amniocentesis. A Cochrane review assessed the increased risk for fetal loss after second-trimester amniocentesis to be <1% (3). Seeds (46) reviewed studies of more than 1000 amniocenteses, each found in the world literature from over three decades. On the basis of data from more than 68,000 procedures, he concluded the following:

- (1) Amniocentesis with concurrent ultrasound guidance in controlled studies appears to be associated with a procedure-related (excess pregnancy) loss of 0.6% (95% CI, 0.31, 0.90).
- (2) The use of concurrent ultrasound guidance appears to reduce the number of punctures and the incidence of bloody fluid. Concurrent ultrasound guidance was associated with a reduced rate of loss when all studies were compared but not among controlled studies.
- (3) Direct fetal needle trauma is rare, and rarely proved, but may occur more frequently than reported because of failure to diagnose and failure of consistent adverse sequelae.
- (4) An increased rate of pregnancy loss in cases of placental puncture is not demonstrated.

Large-scale randomized trials with skilled operators using modern ultrasonographic equipment are needed to better delineate current risks for mid-trimester amniocentesis as the often quoted increased risk of pregnancy loss of 0.5% after amniocentesis may be high.

In conclusion, we believe it is wise to continue to counsel that the risk of pregnancy loss secondary to amniocentesis is 0.5% over baseline, or perhaps slightly less at centers with experienced operators. At our center, we counsel patients that the risks of serious maternal complications and fetal injuries are “remote,” but are not zero (47,48).

### 26.2.2 Early Amniocentesis: 14 Weeks Gestation or Less

With the advent of high-resolution ultrasound equipment, some physicians began offering amniocentesis before 15 weeks gestation. Some programs not offering CVS viewed early amniocentesis as an attractive alternative for those women who desired prenatal diagnosis before the time in pregnancy when traditional amniocentesis is performed

(i.e. 15 weeks gestation or greater). In other medical centers, early amniocentesis was explored to obviate the inconvenience of patients having to be rescheduled if they came in for CVS and were determined to be beyond 12 weeks gestation but under 15 weeks gestation.

A number of programs, including our own center, had reported experiences suggesting early amniocentesis to be a promising technique. In a series of 936 amniocenteses at 12.8 weeks gestation or less reported by Hanson and colleagues (49), loss rates were 0.7% (7 of 936) within 2 weeks of amniocentesis, with an additional 2.2% before 28 weeks and an additional 0.5% stillbirths or neonatal deaths. Total losses (32 of 936, or 3.4%) were considered comparable with the 2.1–3.2% in ultrasonographically normal pregnancies not undergoing a procedure; however, lack of corrections for maternal age and gestational age render comparisons less than exact. Other series reported include those conducted by Benacerraf and colleagues (50), Elejalde and colleagues (51), Penso and colleagues (52), Strippario and colleagues (53), Hackett and colleagues (54), Assel and colleagues (55), Djalali and colleagues (56), Henry and Miller (57), Yang and colleagues (58), Eiben and colleagues (59), and Kerber and Held (60). Our group, then at the University of Tennessee, Memphis (61), compared our initial experience with 250 early amniocenteses (14 weeks or less) to that of our first 250 cases of transabdominal CVS (9.5–12.9 weeks), finding loss rates for early amniocentesis and transabdominal CVS to be 3.8% and 2.1%, respectively. Our group also reported early amniocentesis in six twin gestations (mean 11.9 weeks; range 10.5–13.6 weeks), using a similar dye injection technique as described for traditional amniocentesis (see previous) (62). We successfully tapped both amniotic sacs in each of six cases (five requiring two needle insertions, one requiring three needle insertions); all cultures yielded normal cytogenetic results, and all six pregnancies resulted in the delivery of healthy infants.

However, these studies mostly represented observational reports of amniocentesis with most of the procedures being performed at or after 13 weeks gestation. Comparative studies evaluating the safety and efficacy of early amniocentesis have failed to corroborate the generally favorable outcomes reported in the observational studies. Nicolaides and colleagues (63) reported a comparison of amniocentesis and CVS at 10–13 weeks gestation. Early amniocentesis was performed in 731 patients (493 by choice and 238 by randomization) and CVS in 570 (320 by choice and 250 by randomization). Both procedures were performed by transabdominal ultrasound-guided insertion of a 20-gauge needle. The spontaneous loss (intrauterine or neonatal death) was significantly higher after early amniocentesis (total group mean, 5.3%; CI, 3.8–7.2; randomized subgroup mean, 5.9%; CI, 3.3–9.7) than after CVS (total group mean, 2.3%; CI 1.2–3.9; randomized subgroup mean, 1.2%,

CI 0.3–3.5). Subsequently, Nicolaides and colleagues (64) reported further findings of this study. Again, post-procedure loss rates were significantly higher in the total early amniocentesis group (4.9%) and the randomized early amniocentesis subgroup (5.8%) than in the total transabdominal CVS group (2.1%) and the randomized transabdominal CVS subgroup (1.8%). The frequency of talipes equinovarus was also higher in the early amniocentesis group, but this difference did not attain statistical significance.

Sundberg and colleagues (65) performed a similar type of randomized trial comparing early amniocentesis and CVS. In this study, the rate of talipes equinovarus was significantly increased in the early amniocentesis group, despite the fact that the investigators used a filter system to reduce the amount of fluid removed (66). This finding led the authors to prematurely terminate their study for safety concerns.

The results of the Canadian Early Amniocentesis versus Mid-Trimester Amniocentesis Trial (37,67)—a multicenter, randomized trial of early amniocentesis and conventional second-trimester amniocentesis—have been most revealing. This multicenter trial randomized 4374 women into an early amniocentesis cohort ( $n=2183$ ) and a conventional mid-trimester amniocentesis cohort ( $n=2185$ ). In the early amniocentesis cohort, 1916 women (87.8%) underwent amniocentesis before 13 weeks gestation.

Loss rates were 7.6% for the early amniocentesis cohort and 5.9% for the mid-trimester cohort ( $P=0.012$ ). Talipes equinovarus occurred in 1.3% of infants delivered of women in the early amniocentesis group compared with 0.1% in the mid-trimester cohort ( $P=0.0001$ ). In addition, postprocedure amniotic fluid leakage occurred more frequently in the early amniocentesis group (3.5%) than in the mid-trimester group (1.7%;  $P=0.0007$ ). Failed procedure, multiple needle insertions, and culture failure also occurred more frequently in the early amniocentesis group (37,67).

A recent publication of the US National Institutes of Health-sponsored multinational multicenter trial showed somewhat different findings from that of the Canadian trial (68). This prospective randomized trial of amniocentesis and CVS performed between 11 and 14 weeks gestation found a significant fourfold increase in talipes equinovarus among women undergoing amniocentesis compared with women undergoing transabdominal CVS but demonstrated a nonsignificant increase in fetal loss in the amniocentesis cohort. Although there appears to be a modest association between talipes equinovarus and amniocentesis at  $\geq 15$  weeks' gestation, this mainly seems to be confined to children with non-isolated talipes equinovarus. Overall, second-trimester amniocentesis is unlikely to contribute to the development of talipes equinovarus (69).

In summary, the preponderance of data from rigorously performed studies support the concept that

amniocentesis before 14 weeks carries risks that are increased in comparison with first-trimester CVS or second-trimester amniocentesis. Accordingly, most have abandoned the use of early amniocentesis for conventional prenatal diagnosis.

## 26.3 CHORIONIC VILLUS SAMPLING

Because amniocentesis is most commonly performed in the mid-second trimester (15–16 weeks), fetal diagnosis cannot usually be established before 17–18 weeks gestation. A technique that could be performed during the first trimester would be highly desirable to reduce the psychological stress of awaiting results until mid-pregnancy and to allow a safer method of pregnancy termination, should an abnormality be detected. CVS is such a technique.

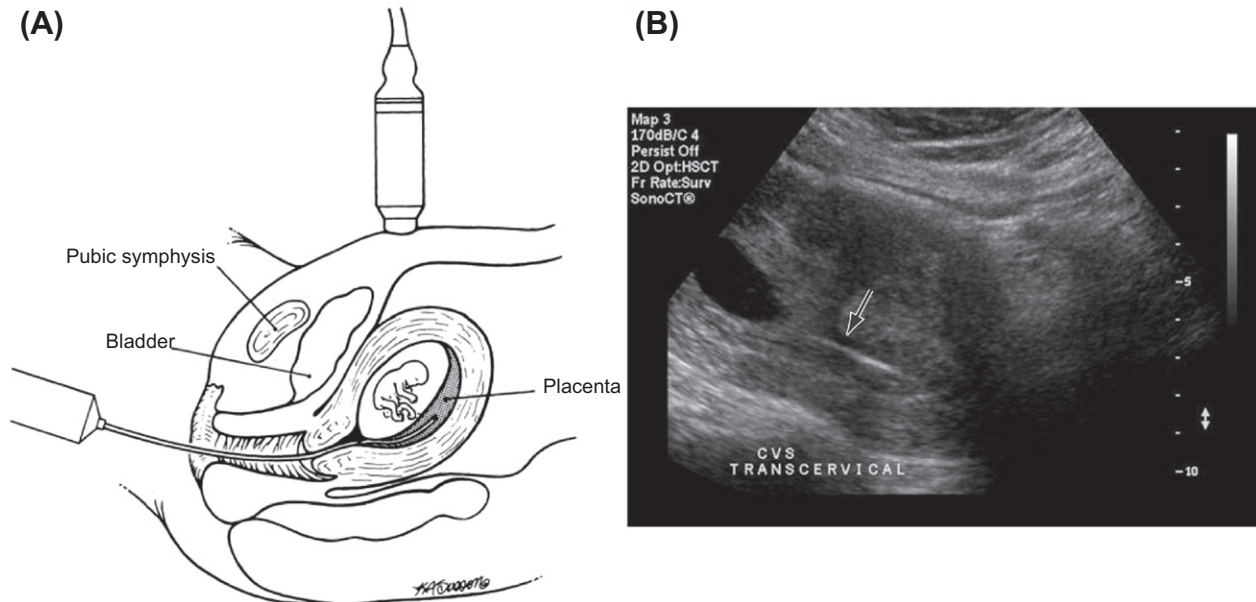

After fertilization, the zygote differentiates first into the blastocyst, which contains an inner cell mass that develops into the fetus and an outer trophoblastic layer that develops into non-fetal structures such as amnion, chorion, and placenta. The genetic complement of the outer cell mass nearly always reflects the genetic constitution of the inner cell mass (i.e. the fetus) because both are derived from the same zygote. It follows that cytogenetic, DNA, or biochemical analysis on trophoblastic cells should provide information comparable with that obtained from cultured amniotic fluid cells. The one major exception is that assays requiring amniotic fluid, specifically AFP, require amniocentesis.

### 26.3.1 Techniques for CVS

**26.3.1.1 Transcervical CVS.** Transcervical CVS is now usually performed at 10–12 completed gestational weeks. Absolute contraindications to transcervical CVS include active cervical or vaginal pathology (e.g. herpes, chlamydia, or gonorrhea infection) or maternal blood group sensitization. Relative contraindications include leiomyoma obstructing the cervical canal, bleeding from the vagina within 2 weeks of planned CVS, and a markedly retroverted, retroflexed uterus (70). Before CVS, fetal viability and normal fetal growth must be confirmed by ultrasound. The procedure is performed with a device that consists of a plastic cannula enclosing a metal obturator extending just beyond the catheter tip; the diameter of most catheters is approximately 1.5 mm.

At our center, CVS is performed in an ultrasound suite. The patient is positioned in the dorsal lithotomy position. The vagina is cleaned with an iodine preparation and the perineum draped with sterile towels. After insertion of a sterile vaginal speculum, placement of a tenaculum on the anterior lip of the cervix may occasionally be needed to help correct uterine anteversion or retroflexion. The CVS catheter is introduced transcervically under simultaneous ultrasonographic visualization, with optimal catheter placement being parallel to the long axis of the placenta (Figure 26-3A,B). The obturator is

**FIGURE 26-3** (A) Transcervical CVS. (From Elias, S.; Simpson, J. L. *Techniques and Safety of Genetic Amniocentesis and Chorionic Villus Sampling*. In *Diagnostic Ultrasound Applied to Obstetrics and Gynecology*, 3rd ed.; Sabbagha, R. E., Eds; JB Lippincott: Philadelphia, 1994, with permission.) (B) Ultrasonographic visualization of transcervical CVS. Catheter is coursing through the cervix (arrow), with catheter tip in the substance of the placenta. (Courtesy of Leeber Cohen, MD.)

then withdrawn and the catheter Luer-lock attached to a 20- or 30-mL syringe. Chorionic villi are then aspirated by multiple, rapid aspirations of the syringe plunger to 20- to 30-mL negative pressure. The catheter is withdrawn under continuous maximum negative pressure. An adequate sample is at least 5mg of villi, but a sample of 10–25 mg is preferred.

After the procedure, fetal heart activity is verified by ultrasonography. Patients are monitored for any untoward effects for approximately 30 min. Unsensitized Rh-negative patients are given RhIg. Maternal serum AFP screening for fetal neural tube defects is recommended at 16–18 weeks gestation.

**26.3.1.2 Transabdominal CVS.** Transabdominal CVS can be used to evaluate pregnancies at the same gestational age as transcervical CVS at 10–12 weeks; however, this procedure also can be performed later in pregnancy (71–73), particularly when fetal abnormalities are visualized at ultrasound and a rapid diagnosis may influence pregnancy management. Placentas, especially amenable to the transabdominal approach, include those located in the fundus or those located anteriorly in an anteфлекed uterus. Transabdominal CVS is also an option in certain circumstances when transcervical sampling is contraindicated (e.g. active genital herpes or cervical lesions).

After selection of a needle-insertion site based on ultrasound findings, the overlying skin is infiltrated with a local anesthetic, cleaned with an iodine preparation, and draped with sterile towels. As performed at our centers, a 19-gauge spinal needle is inserted percutaneously through the maternal abdominal wall and myometrium under continuous ultrasound guidance.

The tip is then guided into the long axis of the placenta (Figure 26-4A,B). The needle stylet is withdrawn, and next a syringe housed in an aspiration device (Cameco syringe pistol, Precision Dynamics, San Fernando, CA) is connected to the Luer-lock of the needle. Chorionic villi are obtained by repeated (15–20) rapid aspirations of the syringe plunger to 20 mL of negative pressure. The needle is then withdrawn under continuous negative pressure. The same postoperative protocol is used as for transcervical CVS.

Most physicians performing transabdominal CVS employ the aforementioned “free-hand” technique. Alternatively, some operators still use a guide-needle or double-needle system device, which punctures the uterine wall once but permits multiple attempts at villus aspiration (74).

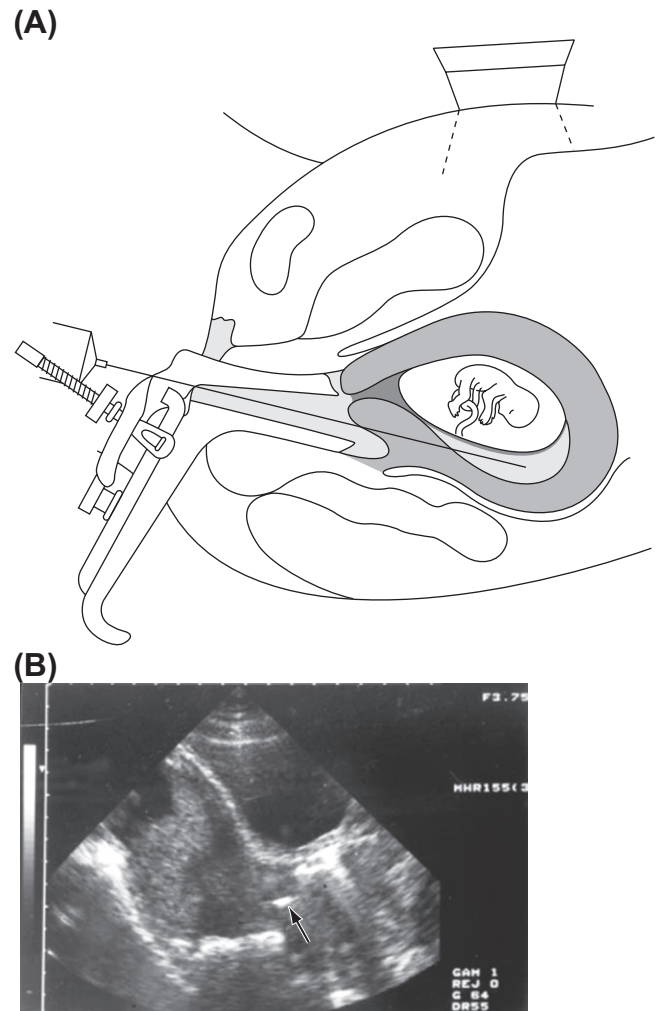

**26.3.1.3 Transvaginal CVS.** Although not commonly necessary, transvaginal CVS may be the only option in women having a retroverted, retroflexed uterus with a posterior placenta. Patients are prepared in a manner similar to transcervical CVS. We use a 35-cm 18-gauge aspiration needle to obtain chorionic villi. The wall of the vagina posterior to the cervix is infiltrated with a local anesthetic. Transabdominal ultrasound is used for needle guidance through the vaginal mucosa and myometrium into the placenta. Once within the placenta, the needle stylet is removed, and villi are aspirated in a similar manner as with transabdominal CVS (Figure 26-5A,B; (75)). Although anecdotal assessment of the safety of transvaginal CVS does not suggest an increased risk of fetal loss or other adverse outcomes, a rigorous assessment of the safety and efficacy of this procedure has not been performed.

**FIGURE 26-4** (A) Transabdominal CVS. (From Elias, S.; Simpson, J. L. *Techniques and Safety of Genetic Amniocentesis and Chorionic Villus Sampling*. ### 26.3.2 Safety of CVS

**26.3.2.1 Pregnancy Loss after CVS.** The U.S. Cooperative Clinical Comparison of CVS and Amniocentesis study and the Canadian Collaborative

**FIGURE 26-5** (A) Transvaginal CVS. (B) Ultrasonographic visualization of transvaginal CVS. Arrow points to needle tip about to enter uterine wall. (Figure 26-5A,B originally published in "Shulman, L.P. et al. *Prenat. Diagn.* 1992, 12, 229–234".)

CVS–Amniocentesis Trial Group study initially reported the pregnancy loss rate of CVS to be 0.8% and 0.6% higher than traditional amniocentesis, respectively (76,77). Neither figure was statistically significant. In the US study, 2278 women self-selected transcervical CVS; 671 women similarly recruited in the first-trimester-selected amniocentesis. Randomization did not prove possible. The Canadian study was randomized, with 1391 subjects assigned to transcervical CVS and 1396 to amniocentesis. Variables shown to influence fetal loss rates adversely included fundal location of the placenta, number of catheter passages, small sample size, and prior bleeding during the current pregnancy (77,78). Almost all the above invariably reflect technical difficulty. Other obstetric complications (e.g. intrauterine growth restriction (IUGR), placental abruption, premature delivery) did not exceed those in women not undergoing CVS.

Transcervical CVS and transabdominal CVS appear to be equally safe procedures for first-trimester diagnosis when the approach is chosen based on placental location and ease of procedure. In a later US NICHD collaborative study, in which 1844 patients were randomized to transcervical CVS and 1929 patients to transabdominal CVS, the loss rates of cytogenetically normal pregnancies through 28 weeks were 2.5% and 2.3%, respectively (79). Of note, the overall loss rate (i.e. background plus procedure related) after CVS decreased by about 0.8% during this 1988–1990 randomization trial, in comparison with rates observed during the transcervical versus amniocentesis self-selection study (1985–1987). This decrease in procedure-related loss rate probably reflects increasing operator experience, as well as availability of both transcervical and transabdominal approaches. In a small Italian randomized trial, Brambati and colleagues (80) also found no difference between transabdominal and transcervical CVS. By contrast, in a randomized comparison of amniocentesis, transabdominal CVS, and transcervical CVS in Denmark, Smidt-Jensen and colleagues (81) found similar fetal loss rates after transabdominal CVS and amniocentesis but a significantly increased loss rate associated with transcervical CVS. These results are not surprising, however, as Danish experience with transabdominal CVS was far greater than with transcervical CVS.

One major study that substantively differs from the United States, Canadian, and Italian collaborative trials is the Medical Research Council Study (82). In this multicenter randomized comparison between first-trimester CVS performed by any approach deemed suitable by the obstetrician and second-trimester amniocentesis, the ultimate variable measured was completed pregnancies. The 4.4% fewer completed pregnancies in the CVS cohort reflected both unintended and intended pregnancy terminations. The latter, in turn, probably reflected inexperience in cytogenetic interpretation, given some terminations seemingly arguable in retrospect (i.e. confined placental mosaicism). Experience with CVS by the MRC study operators was also considerably less than in the US operators. For example, the only requirement for participation in the MRC study was 30 “practice” CVS procedures. Some centers also contributed very few cases.

No formal attempts to assess the safety of transvaginal CVS have as yet been attempted. In our own experience (75), as well as that of Sidransky and colleagues (83), neither major complications nor obvious excessive fetal loss rates have been observed.

There have now been a number of assessments of the safety of CVS come from randomized trials evaluating the safety of CVS. Sundberg and colleagues (65) found a total risk of loss among 579 women randomized to transabdominal CVS to be 4.8%. In a more recent study sponsored by the US NICHD, 2.1% of cytogenetically normal pregnancies exposed to transabdominal CVS at

11–14 weeks inclusive resulted in fetal loss or preterm delivery before 28 weeks gestation (84). Such information confirms earlier studies of the risks of transabdominal CVS.

More recently, Caughey and Colleagues (85) reported a retrospective cohort study of all amniocentesis and CVS procedures resulting in a normal karyotype from 1983 to 2003 at the University of California, San Francisco. In a comparison of 9886 CVS and 30,893 amniocentesis procedures performed during the study period, the overall loss rates were 3.12% for CVS and 0.83% for amniocentesis ( $P < 0.001$ ). However, in the most recent time period, 1998–2003, there was no difference between the two procedures (adjusted odds ratio 1.03, 95% CI 0.23–4.52). The authors concluded that “...there is no longer a statistically significant difference between the two (procedures).” In reviewing the extant data, the American College of Obstetricians and Gynecologists has similarly concluded that “In experienced individuals and centers, CVS and amniocentesis procedure-related loss rates may be the same as those for amniocentesis.” (86).

We conclude that clinical judgment and patient individualization in choosing the optimal approach for CVS increases safety. For example, some technically difficult transcervical CVS procedures (e.g. fundal placentas) should be avoided in favor of a technically more facile transabdominal approach. The converse is also true.

**26.3.2.2 CVS in Multifetal Pregnancy.** CVS in multifetal pregnancies has become more widely used with increasing use of fetal reduction resulting from assisted reproductive technologies (ART). Many women requiring ART to become pregnant are also at increased risk for fetal chromosome or Mendelian abnormalities, primarily because of advanced maternal age. CVS before fetal reduction allows for the detection of chromosome or DNA abnormalities, thus allowing for the reduction of only abnormal gestations (87–90).

Few data exist for the safety of CVS in multiple gestations. In a major US study involving four centers, the total loss rate of chromosomally normal fetuses (spontaneous abortions, stillborns, neonatal deaths) was 5.0% (91), only slightly higher than the 4.0% observed for singleton pregnancies (77). Brambati and colleagues (88) reported no differences in fetal and perinatal loss rates among 198 sets of twins undergoing CVS compared with a matched cohort of twin pregnancies not undergoing invasive prenatal diagnosis. Brambati and colleagues (92) reported their ongoing experience with CVS before multifetal reduction. Prenatal diagnostic and clinical outcomes of 424 multiple pregnancies reduced to twins ( $n = 255$ ) or singletons ( $n = 169$ ) were compared with 147 twin- and 885 singleton-matched controls, in which reduction procedures were not performed. Transabdominal CVS was successfully performed in 100% of cases with an accuracy of 99.2%. The overall loss rate after reduction was 3.3%; no significant differences in overall pregnancy loss, low birth weight, severe prematurity, or neonatal death

were observed in the two study groups. However, mean gestational age at delivery and mean birth weight were significantly lower in the reduction cohort. The authors concluded that the safety and efficacy of transabdominal CVS before multifetal reduction warrants its consideration for women who desire prenatal diagnosis in such situations. Most recently, Simonazzi and colleagues (93) reported a retrospective cohort study of 204 twin pregnancies who underwent amniocentesis ( $n=100$ ) or CVS ( $n=104$ ). The fetal loss rate <24 weeks was 3.85% in the CVS group and 4.00% in the amniocentesis group ( $P=0.95$ ).

We perform CVS in multiple gestations when the placentas can be reliably sampled by any technique as determined by ultrasonography. When placental locations preclude the reasonable obtainment of separate and distinct samples, second-trimester amniocentesis is preferred.

**26.3.2.3 Limb-Reduction Deformities.** Evaluation of the safety of CVS has recently shifted focus from concerns about the risk of fetal loss to its being the possible cause for congenital abnormalities. In 1991, Firth and colleagues (94,95) reported that 5 of 289 (1.7%, or 17 in 1000) infants exposed to CVS at 56–66 days of gestation (i.e. 42–50 days after fertilization) had severe limb-reduction deformities (LRDs). Four of the five infants had oromandibular-limb hypogenesis (all transabdominal CVS); the fifth had a terminal transverse limb reduction alone (transcervical CVS). Subsequently, a number of reports followed, both supporting and refuting such an association (96–101). In the United States, Burton and colleagues (102) reported a second cluster among 394 infants, whose mothers had undergone CVS. Thirteen (3.3%) had major congenital abnormalities, including four with transverse LRD (10 of 1000, or 1%). All four LRDs were transverse distal defects involving hypoplasia or absence of the fingers and toes. Three of these cases followed transcervical sampling, using a device that, in the hands of the reporting physicians, was associated with an 11% fetal loss rate.

Teratogenic mechanisms whereby CVS might cause LRDs have been hypothesized (103). These include (1) hypoperfusion due to fetomaternal hemorrhage or pressor substances released by disturbance of villi or the chorion; (2) embolization of chorionic villus material or maternal clots into the fetal circulation; and (3) amniotic puncture and limb entrapment in exocoelomic gel.

The potential association of LRDs with CVS has been explored through various registries. On the basis of data from the Italian Multicenter Birth Defects Registry, Mastroiacovo and colleagues (104) reported that eight cases of oromandibular–limb hypogenesis complex were entered into the registry from January 1988 through December 1991, four of which had been exposed to CVS, compared with 36 exposed subjects among 8445 controls. There were 166 cases of transverse limb defects alone, four having been exposed to CVS, compared

with 36 cases among 8445 controls. A 1994 update of this study, based on 11 CVS-exposed cases, continued to indicate an association with transverse limb defects (105). The highest risk was associated with procedures performed at <70 days gestation (OR 23.2; 95% CI 1.31–41.0); a lower, but still increased risk with procedures at 70–76 days (OR 17.1; 95% CI 6.7–44.0); over 44 days, there were no exposed cases and the risk interpreted as considerably lower. By contrast, analysis of other European registries in aggregate involving more than 600,000 births showed that only 4 of 336 cases (1.2%) with limb-reduction abnormalities had been exposed to CVS, compared with 78 of 11,883 (0.66%) cases with other malformations (OR 1.8, 95% CI 0.7–5.0) (106).

Firth and colleagues (107) summarized LRDs in 75 infants exposed to CVS by combining their own cases with those reported in the literature. The median gestational age at CVS ranged from 56 (range, 49–65) postmenstrual days for the most severe defects to 72 (range, 51–98) for the least severe. They concluded that there was a correlation between the severity of the defects and the duration of gestation when CVS was performed.

In 1994, the US Centers for Disease Control and Prevention (CDC) held an open forum in Atlanta where data were presented from a US multistate case-control study in an effort to quantify the risk of LDR associated with CVS (108). Case subjects were 131 infants with non-syndromic limb deficiency from seven population-based birth defects surveillance programs born to women 34 years or older from 1988 through 1992. Controls were 131 infants with other birth defects matched to case subjects by the infant's year of birth, mother's age, race, and state of residence. Overall, the odds ratio for limb deficiency after CVS from 8 to 12 weeks gestation was 1.7 (95% CI 0.4–6.3). However, when analyzed for specific anatomic subtypes, there was an association for transverse digital deficiency (OR 6.4; 95% CI 1.1–38.6). They concluded that the absolute risk for such defects was approximately 1 in 3000. It should be noted that such transverse digital deficiencies occurred in only seven exposed cases.

Finally, the World Health Organization Committee on CVS analyzed data collected through an international voluntary registry (109,110). A total of 77 cases with LRDs among 138,996 infants born after CVS was reported from 63 registering centers. Pattern analysis of the types of limb defects and overall frequencies of specific LRDs were compared with a background population study from British Columbia (111). The pattern of defects showed upper limb to be affected in 65%, 13% in the lower limb, and 23% in both upper and lower limbs compared with frequencies in the general population of 68%, 23%, and 9%, respectively. Transverse limb defects occurred in 41% of infants in the cohort exposed to CVS, compared with 43% in the general population, and longitudinal limb deficiencies were found in 59% of cases, compared with 57% in the

general population. It was concluded that the pattern analysis of the types of limb defects and calculation of overall incidences failed to find a difference between the CVS and background populations.

A review of CVS safety sponsored by the World Health Organization (112) evaluated the clinical outcomes of 216,381 CVS cases performed worldwide. In this review, a total of 115 LRDs were observed with an incidence of 1/1881, similar to the rate of 1/1642 observed in the general population. The distribution of LRD (upper limbs 71.3%, lower limbs 11.3%, both limbs 17.4%) was also similar to that observed in the general population. The authors concluded the data demonstrate that "...CVS carries no increased risk for fetal loss or congenital malformation, including limb reduction defect..." compared with conventional mid-trimester amniocentesis.

A recent controversy has arisen as to a possible association between CVS and preeclampsia (113). Our group at Northwestern University, Chicago, IL, reported 653 women who underwent prenatal diagnosis (501 by amniocentesis and 152 by CVS) who were matched by age with 653 women who did not undergo invasive prenatal diagnosis. In multivariate analysis, the factors that remained significantly associated with preeclampsia were (1) maternal age <25 years old (OR 7.4, 95% CI 23.3–23.6); nulliparity (OR 2.7, 95% CI 1.1–6.9); and (3) having had a CVS as a nulliparous woman (OR 4.2, 95% CI 1.4–12.6) (114). Others have failed to show an association between gestational hypertension and preeclampsia with DVS (115,116).

In summary, CVS is the only established method for first-trimester prenatal diagnosis and carries minimal, if any, increased risk for adverse pregnancy outcomes when performed by experienced operators. To maximize the safety of CVS, we avoid performing CVS before 10 weeks gestation except in cases of profound risk for fetal abnormalities (e.g. fetal hydrops). We continue to counsel patients about the LRD controversy and inform them that the absolute risk at 10–12 weeks is believed to be very low, approximately 1 in 2000, a rate similar to that observed in the general population (112). We also stress that this issue be placed in proper perspective and weighed against the substantial advantages that CVS offers first-trimester prenatal diagnosis.

## 26.4 FETAL BLOOD SAMPLING

Access to the fetal circulation was initially accomplished by fetoscopy, a method of directly visualizing the fetus, umbilical cord, and chorionic surface of the placenta, using endoscopic instruments (25,117). Fetoscopy for this purpose has now been replaced by ultrasound-directed percutaneous umbilical blood sampling (PUBS), also termed *cordocentesis* or *funipuncture*.

Fetal blood chromosome analysis has been used to help clarify purported chromosome mosaicism detected

in cultured amniotic fluid cells (118) or chorionic villi. Rapid assessment of fetal chromosome complement has been accomplished by "direct" cytogenetic analysis of uncultured nucleated blood cells (119). Short-term fetal lymphocyte cultures can provide a cytogenetic result within 72 h; direct analysis of spontaneously dividing fetal cells (probably nucleated red blood cells) can provide a karyotype result within 24 h. This proves particularly useful for patients presenting late in the second trimester, when results from amniocentesis would be available only after pregnancy termination would no longer be available. In addition, in cases of fetal structural abnormalities or intrauterine growth retardation (IUGR) presenting in the third trimester, rapid results may prove useful for decision making concerning the mode of delivery (120,121). More recently, fluorescent in situ hybridization (FISH) with chromosome-specific DNA probes has also been used for rapid prenatal diagnosis of aneuploidy using nucleated fetal blood cells from umbilical cord blood, as well as chorionic villus and amniotic fluid cells (122).

Fetal blood sampling is used in the prenatal evaluation of many fetal hematological abnormalities (123). Daffos (124) reported normal hematological values for second-trimester fetuses, and Forestier and colleagues (125,126) reported normal blood chemistry values for second-trimester fetuses. Fetal blood hematocrit can be directly measured to assess hemolysis resulting from Rh or other blood antigen isoimmunization states (127). Before this, obstetricians had to rely on indirect evidence of fetal hemolysis, such as maternal antibody titers, past obstetric history, ultrasound findings, and spectrophotometry of bilirubin in amniotic fluid; the need for subsequent transfusions was based on somewhat arbitrary guidelines. Now the decisions about who, when, how much, and how often to transfuse can be made more rationally on the basis of actual fetal blood analyses such as hemoglobin level, hematocrit level, blood group, direct antibody titer, and reticulocyte count. Fetal hemoglobin can be directly evaluated to diagnose sickle cell disease,  $\alpha$ - or  $\beta$ -thalassemia, or other hemoglobinopathies (117) although these disorders are now usually diagnosed by DNA analysis of chorionic villi or amniotic fluid cells. Fetal blood sampling can also be used to directly assess both the quantity of platelets and the quality of function (128). With regard to maternal PLA2 (platelet antigen) alloimmunization, PUBS is useful not only for diagnosis but also for access to the fetal circulation allowing therapeutic alternatives including in utero platelet transfusion or maternal immunotherapy with gamma globulin or steroids (129).

Fetal blood has been used for the diagnosis of blood factor abnormalities such as hemophilia A, hemophilia B, or von Willebrand disease (126,130). In addition to hematologic studies, fetal blood samples can be used to diagnose autosomal-recessive or X-linked immunologic deficiencies, including severe combined immunodeficiency,

Chédiak–Higashi syndrome, Wiskott–Aldrich syndrome, and chronic granulomatous disease (131–133).

Recovery of fetal blood permits assessment of viral, bacterial, or parasitic infections of the fetus. Detection of fetal viral or parasitic infection is usually made on the basis of maternal antibody titers or ultrasound-detected fetal structural abnormalities. Serum studies of fetal blood allows for quantification of antibody titers (134,135). In addition to antibody studies, PUBS can be used for direct analysis of viral, bacterial, and parasitic infections by culture of fetal blood (134,136,137).

Although many of the indications for detecting fetal abnormalities that previously required fetal blood sampling are now performed by amniocentesis or CVS using DNA analysis (122,138,139), the continuing value of fetal blood sampling lies not only with those few remaining diagnostic indications but also in providing the potential for drug therapy. For example, fetal arrhythmias have been treated with direct administration of antiarrhythmic medications, and fetal paralysis may be induced to facilitate invasive procedures such as fetal transfusions or for magnetic resonance imaging (MRI) (140).

### 26.4.1 Technique

Today, the technique most commonly used for fetal blood sampling is ultrasound-directed PUBS. The procedure can be safely undertaken from 18 weeks onward although successful procedures have been reported as early as 12 weeks (141,142).

PUBS can be performed as an outpatient procedure. Maternal sedation is usually unnecessary, but oral benzodiazepine 1 or 2 h before the procedure may be of benefit to the anxious patient and usually results in a transient decrease in fetal movement that can facilitate the procedure. A preliminary ultrasonographic examination of the fetus is performed to assess fetal viability, placental and umbilical cord location, fetal or placental anomalies, and fetal position. A suitable site for needle insertion is then selected; the skin over this site is anesthetized with 5 mL of 1% xylocaine. A sterile field is established; the skin is cleansed with an iodine-based solution and sterile drapes applied. The ultrasound transducer is placed on the abdomen away from the sterile insertion site but at a location that permits visualization of the complete path of the needle from skin to fetal blood vessel.

There are several potential sampling sites. Owing to its fixed position, the placental cord root is usually the site of choice whenever it is clearly visible. Alternatively, free loops of cord or the intrahepatic vein are possibilities (123,143,144). After percutaneous insertion of the spinal needle into the fetal blood vessel under direct ultrasound guidance, a small amount of blood is aspirated. The presence of fetal blood in this initial sample is confirmed using a model ZBI Coulter counter and channelizer to differentiate fetal from maternal blood on the basis of erythrocyte volume. The amount of blood

aspirated for diagnosis depends on the indication for PUBS; rarely more than 5 mL is required.

Upon completion of the fetal blood sampling, the spinal needle is withdrawn, and an ultrasound examination is performed to evaluate fetal status. The woman and her fetus are monitored for about 1 h after PUBS. At our centers, all women at risk of Rh-isoimmunization receive 300 µg of Rh immunoglobulin after the procedure.

### 26.4.2 Safety

Fetal blood sampling appears to be a relatively safe procedure when performed by experienced physicians, albeit carrying more risk than CVS or amniocentesis. Maternal complications are rare but include amnionitis and transplacental hemorrhage (130,145). Data from large perinatal centers estimate the risk of in utero death or spontaneous abortion to be 3% or less after PUBS (124,135,136,146–152). Collaborative data from 14 North American centers, sampling 1600 patients at varying gestational ages and for a variety of indications, revealed an uncorrected fetal loss rate of 1.6% (153).

A more recent assessment of fetal blood sampling loss risk was performed by Antsaklis and colleagues (154), who reviewed their clinical outcomes based on indication for fetal blood sampling. They divided their cohort into five main indication subgroups and found highly significant differences in procedure-related loss rates between the five groups. The highest loss rates were observed in the two groups characterized by fetal abnormalities and growth restriction, thus demonstrating that indication for fetal blood sampling has a major impact on risk for the procedure. In addition to the indication for fetal blood sampling, the technique used to obtain fetal blood (e.g. arterial puncture) (150), and prolonged postprocedure fetal bradycardia (155) may presage an increased risk for adverse clinical outcomes. However, performing cordocentesis in a pregnancy characterized by a single umbilical artery does not appear to increase the risk for procedure-related loss (156,157).

Unfortunately, no studies directly comparing loss rates in control and treated groups have yet been published. Nonetheless, the genetic delineation of an increasing number of Mendelian disorders has and will continue to decrease the need for fetal blood sampling to evaluate pregnancies at increased risk for a wide variety of congenital and acquired conditions.

## 26.5 FETAL TISSUE SAMPLING

Advances in gene and protein identification as a result of the Human Genome Project and other public and private genetic initiatives has considerably reduced the need for fetal tissue biopsy for the prenatal detection of genetic disorders. Conditions such as fetal genodermatoses and Duchenne muscular dystrophy once required fetal skin and muscle biopsy, respectively, for direct pathological

evaluation. However, most of these conditions have been associated with specific gene mutations and are now amenable to diagnosis by CVS, amniocentesis preimplantation genetic diagnosis (PGD) (158,159).

With regard to congenital genodermatoses, fetal skin biopsies were required for ultrastructural or immunohistochemical analysis. Genodermatoses in which prenatal diagnosis has been established by fetal skin sampling have included anhidrotic ectodermal dysplasia (160), bullous congenital ichthyosiform dysplasia (epidermolytic hyperkeratosis) (161–163), epidermolysis bullosa dystrophica (Hallopeau–Siemens) (164), harlequin ichthyosis (165,166), hypohidrotic ectodermal dysplasia (167), epidermolysis bullosa lethalis (168,169), nonbullous ichthyosiform erythroderma (170), and Sjögren–Larsson syndrome (171). One of the more common lethal genodermatoses, Herlitz junctional epidermolysis bullosa, is now amenable to prenatal diagnosis by DNA analysis (172). However, the prenatal diagnosis of harlequin ichthyosis still requires fetal skin sampling, although Akiyama and colleagues (173) have reported that the diagnosis can now be made earlier than 21–22 weeks gestation and recent attempts to use 3D ultrasound to detect affected fetuses have generally been successful (174,175).

On rare occasions, fetal skin sampling is still required and is best performed at 17–20 weeks gestation. The procedure was initially performed under direct visualization using fetoscopy, a procedure associated with a total fetal loss rate of 4–7% (176,177), or a procedure-related loss rate of perhaps 2%. From a safety standpoint, it seemed reasonable to assume that the smaller the caliber of the instrument introduced into the uterus, the safer the procedure. For this reason, we began to use ultrasound-directed biopsy forceps for fetal skin sampling in the 1980s (Figure 26-6; (178)). We reported the clinical outcomes of 17 ultrasound-guided fetal skin sampling procedures (178). In five cases, a fetal skin disorder was diagnosed, and these pregnancies were terminated. In the remaining 12 cases, all infants were delivered without complications at 37 weeks gestation or later. Despite the use of biopsy forceps that take smaller fetal skin samples than the biopsy forceps used for fetoscopically directed fetal skin sampling, superficial scarring lesions have occasionally been noted.

Prenatal diagnosis of Becker–Duchenne muscular dystrophy is usually possible by DNA analysis. However, in a few families, meiotic recombination or homozygosity of multiple restriction fragment length polymorphisms precludes a DNA-based diagnosis (179–181). In these cases, fetal muscle biopsies can be used for immunohistochemical analysis with a fluorescent antidystrophin antibody. Males with Duchenne muscular dystrophy lack dystrophin and with Becker muscular dystrophy lack or demonstrate a variable dystrophin pattern (182), whereas muscle biopsies from unaffected male fetuses show normal amounts of dystrophin.

**FIGURE 26-6** Fetal skin sampling. (From Elias, S.; Emerson, D. S.; Simpson, J. L., et al. *Ultrasound-Directed Fetal Skin Sampling for Prenatal Diagnosis of Genodermatoses*. *Obstet. Gynecol.* 1994, 83, 337, with permission.)

Fetal muscle sampling is usually performed at around 18 weeks gestation using a technique analogous to fetal skin sampling or fetal liver sampling. Muscle biopsies are taken from the gluteal region by directing a Klear Kut (Baxter, Los Angeles, CA) kidney forceps gun toward the fetal buttock. As with fetal skin and liver biopsy procedures, only a small number of fetal muscle sampling procedures have been reported (179,183,184). Thus, statements cannot be made concerning the safety of this procedure.

## 26.6 COELOCENTESIS

Coelocentesis involves the transcervical or transabdominal aspiration of fluid from the extraembryonic celom. This procedure has been suggested as a possible method for early first-trimester prenatal diagnosis. Jurkovic and colleagues (185) were successful in aspirating fluid from 48 to 50 (96%) pregnancies between 6 and 10 weeks gestation. Although the authors were unable to obtain metaphase analyses from these specimens, subsequent work by Cruger and colleagues (186,187) demonstrated success in culturing and karyotyping. In addition, Makrydimas and colleagues (188) reported successful prenatal detection of  $\beta$ -thalassemia by coelocentesis. Among coelocentesis procedures performed on 14 women performed before pregnancy terminations at 8–9 weeks' gestation, Jourannic and colleagues (189) found that coelomic fluid–DNA PCR analysis without marked

maternal contamination was only achieved in 8 of the 14 (58%) of samples.

However, Ross and colleagues (190) reported that short-term pregnancy loss rates associated with coelocentesis were markedly increased. In a comparative study of women undergoing pregnancy termination, 25% of women spontaneously aborted before their termination compared with 5% of women not undergoing coelocentesis ( $P < 0.01$ ). These high loss rates suggest that coelocentesis may not be appropriate as a routine prenatal diagnostic test.

Of interest is the work of Santolaya-Forgas and colleagues. This group has investigated coelocentesis in baboons to determine its potential applicability for fetal therapy. In one series, coelocentesis was performed in nine baboons; fluid aspiration (1–5 mL) was successful in eight cases, and seven of the eight pregnancies were continuing 140 days after the procedure (191). Coelocentesis was subsequently performed in six other baboons; assessment of the extracoelomic fluid osmometry and electrolyte composition in these six samples found that the chorion laeve behaves as a semipermeable membrane at 40 days gestation (192), suggesting that it may be useful for maternal–fetal transfer of some substances that could be used for fetal therapy.

## 26.7 EMBRYOSCOPY

Embryoscopy remains an investigational technique that permits direct visualization of the fetus as early as the first trimester (193–195). Initially, a rigid fiberoptic endoscope was passed transcervically into the extracoelomic cavity, permitting inspection of fetal anatomic structures; fetal blood sampling was also feasible by this method (194). However, improvements and advancements in fiberoptic technology have led to the performance of thin-gauge transabdominal and transcervical embryoscopy (196), allowing visualization as early as 4 weeks after conception (197).

Initial procedures were performed only on women who had elected pregnancy termination; however, embryoscopy has since been performed on continuing pregnancies (194). Ville and colleagues (198) reported a procedure-related loss rate of 12% when the procedure was performed in the first trimester.

Further and larger studies of the safety, accuracy, and applications of this new modality will be needed before embryoscopy is used as a routine prenatal diagnostic tool. However, the ability to access the embryonic circulation may have important application for therapeutic interventions such as drug, gene, and cell therapy.

## 26.8 POLAR BODY BIOPSY

Polar body biopsy involves micromanipulation to remove either the first or the second polar body, and subsequent genetic analysis. This approach allows the oocyte to

remain viable for embryo development. Verlinsky and colleagues (Verlinsky et al., 1990) pioneered polar body biopsy genetic diagnosis using PCR to identify single-gene disorders in first polar bodies and transfer of unaffected embryos. For example, if a woman is heterozygous for an autosomal-recessive disease, a polar body having the mutant allele should be complemented by a primary oocyte presumed to have the normal allele. Thus, the oocyte could be used for in vitro fertilization (IVF) and transfer. Conversely, if the polar body was determined not to carry the mutant allele, the oocyte would contain the mutant allele and not be fertilized. A disadvantage is recombination, the meiotic phenomenon that occurs routinely between homologous chromosomes. Diagnostic difficulties resulting from recombination are a greater problem for genes located nearer the telomeres because these genes display recombination approximately 50% of the time. To detect hemizygous normal oocytes resulting after the second meiotic division, analysis of the second polar body is needed. The most accurate diagnosis can be achieved when the first polar body is heterozygous, so that detection of the normal or mutant gene in the second polar body indicates the opposite mutant or normal genotype of the resulting maternal contribution to the embryo. Similar to single-gene disorders, aneuploidy can be deduced. For example, if the first polar body failed to show a chromosome 21, the oocyte would be presumed to have two 21 chromosomes, and hence, the zygote would have trisomy 21. However, sequential testing of blastomere(s) is still required to exclude rarer paternally derived abnormalities (199).

## 26.9 PREIMPLANTATION GENETIC DIAGNOSIS

PGD is a technique that combines IVF with genetic analysis of the embryo. As only unaffected embryos are transferred to the uterus for implantation, PGD provides an alternative to invasive postconception procedures, i.e. CVS or amniocentesis.

PGD has been performed for a large number of single-gene disorders over the past two decades, and today the basic requirement for PGD is identification of the specific gene mutation in the family. These include X-linked, autosomal recessive, and autosomal dominant disorders (200). However, the most common indication for PGD detection of chromosomal abnormalities, numerical or structural, either by FISH, or genome-wide molecular approaches such as single cell array comparative genome hybridization testing for genome-wide single nucleotide polymorphisms (201–204), chromosomal aberrations, particularly aneuploidy, is known to be associated with early spontaneous abortions, it was believed that success rates for IVF and other forms of ART could be improved by so-called preimplantation genetic screening (PGS). The intent of such screening is to improve live birth rates by excluding chromosomally abnormal

embryos for transfer in IVF. The main indications for PGS are advanced maternal age, recurrent implantation failures, and recurrent spontaneous abortions. Initial studies suggested favorable effects on pregnancy success with PGS, but randomized controlled trials have not shown that PGS increases the delivery rate (205). The American College of Obstetricians and Gynecologists has indicated that there are no data to support use of PGS for recurrent spontaneous abortions and recurrent implantation failures, and its use for these indications be restricted to research studies (206). Finally, PGD has been used to determine the human leukocyte antigen (HLA) of embryos to produce a child that can serve as an HLA-matched hematopoietic stem cell donor for transplantation to a sibling, who is affected with a condition such as leukemia or lymphoma (207).

The most widely used method for PGD is blastomere biopsy at the cleavage (6–8 cell) stage of embryonic development. This technique involves disruption of the zona pellucida with a laser drilling or chemical means followed by insertion of a micropipette and aspiration of one or two blastomeres. Alternatively, the blastocyst stage is reached on day 5 or 6 after fertilization and allows the removal of multiple cells from the early trophoblast; however, this approach has not been widely applied.

Removal of one or more blastomeres does not appear to convert a significant risk of congenital anomalies to subsequent infants as reviewed recently by Simpson (208).

## 26.10 ULTRASONOGRAPHY

Ultrasonography has been one of the most important advances in the practice of obstetrics. At intensities usually produced by diagnostic equipment, ultrasound has not been found to cause any harmful effects on pregnant women, fetuses, other patients, or operators (209–211). Indications for ultrasonography during pregnancy are multiple and diverse and include estimation of gestational age by biometric measurements, estimation of fetal growth, bleeding from the vagina, determination of fetal growth, suspected multiple gestation, adjunct to invasive procedure (e.g. CVS or amniocentesis), suspected uterine or adnexal abnormality, suspected fetal demise, and many others (212,213).

In the context of prenatal diagnosis, many major, and even some minor, fetal structural anomalies can now be reliably detected. It is unrealistic, however, to expect 100% accuracy in detecting fetal anomalies, even with the most expert and thorough scanning. Some anomalies are more readily diagnosed than others. For example, anencephaly and marked hydrocephaly are rarely misdiagnosed, whereas others are more difficult to diagnose and may be overlooked, such as heart defects, facial clefts, diaphragmatic hernias, skeletal abnormalities, and neural tube defects (212–214).

Although there is no question that high-resolution ultrasonography is invaluable in detecting fetal anomalies (213–215), accuracy of diagnosis will vary depending on the experience of the sonographer, as well as on equipment, gestational age at time of scanning, and the *a priori* risk of the abnormality in question (216–219). As such, the limitations of diagnostic ultrasonography must be recognized. For example, in an admittedly dated study, Platt and colleagues (220) reviewed the ultrasound findings in 161 fetuses with spina bifida identified in the California MSAFP screening program. Before information regarding elevated MSAFP was made available to the examiner, in 13 of the 161 cases, spina bifida was not initially visualized. Subsequently, the defect was found in 10 of the 13 fetuses; in the remaining three cases, amniocentesis was declined, and the spina bifida was only diagnosed at birth. In screening for fetal anomalies, data concerning the sensitivity, specificity, and predictive values of diagnostic ultrasound are usually not available (68).

Although most women today receive one ultrasound examination during pregnancy, controversy still persists as to whether ultrasound monitoring of all obstetric patients should be routine to screen for fetal structural anomalies. These issues were first addressed in a report from the NICHD-sponsored Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) study (221). Low-risk pregnant women with no indication for ultrasonography were randomly assigned to have either two screening sonograms (15–22 weeks and 31–35 weeks) or conventional obstetric care with ultrasonography used only on a selective basis as determined by the clinical judgment of the patient's physician. Major congenital anomalies occurred in 2.3% of the 15,281 fetuses and infants. Antenatal ultrasonography detected 35% of the anomalous fetuses in the screened group vs only 11% of the control population (relative detection rate 3.1; 95% CI 2.0–5.1). Surprisingly, ultrasonography did not significantly influence the management or outcome of pregnancies complicated by fetuses with congenital malformations. Moreover, ultrasonography screening had no significant impact on survival rates among infants with potentially treatable, life-threatening anomalies despite the opportunity to take precautionary measures such as delivery at a tertiary center. The RADIUS study also provided some insight into the content and limitations of obstetric ultrasound examinations. For example, a four-chamber view of the heart permitted detection of only 43% of fetuses with complex heart disease, and only 30% of fetuses with cleft lip and palate were detected. Finally, it was estimated that a public health policy of routine ultrasonographic screening would increase US health care costs by at least \$500 million. This study concluded that “given this extraordinary cost and the lack of measurable benefit, ultrasonographic screening for fetal anomaly detection cannot be justified.”

Many groups and centers subsequently reevaluated the RADIUS findings as well as their own experience and came to the opposite conclusion. DeVore (222) reported that the RADIUS study demonstrated that second-trimester ultrasonography could be provided in a cost-effective manner to low-risk women. Skupski and colleagues (223) reported on their experience with ultrasound in a low-risk population and found that the detection of major and minor malformations had a profoundly positive impact. The Eurofetus Study (224) combined the ultrasound and clinical outcomes of 61 European centers over a 3-year period and found that systematic ultrasound pregnancy detected a large proportion of fetal malformations. In 2009, the American College of Obstetricians and Gynecologists published a Practice Bulletin on the topic *Ultrasonography in Pregnancy* (206). Included in the clinical considerations and recommendations, it was pointed out that ultrasonography can be used to diagnose many major fetal anomalies, and that it has been suggested that all patients be offered routine ultrasound screening, given that 90% of infants with congenital anomalies are born to women with no risk factors. However, patients should be counseled about the limitations of ultrasonography and the sensitivity of the examination for the detection of abnormalities and potential false-positive findings. Ideally, all women should be offered aneuploidy screening before 20 weeks gestation, regardless of maternal age. For women presenting before 14 weeks gestation, the option for first-trimester screening is available, which includes measurement of nuchal translucency as a component for Down syndrome and trisomy 18 screening (discussed below). A second-trimester ultrasound examination may show indications of fetal chromosome abnormalities, including echogenic bowel, intracardiac echogenic focus, short femur or humerus, and dilated renal pelvis; these markers have a low sensitivity and specificity for Down syndrome, particularly in a low-risk population. However, ultrasound evaluation is not recommended as a primary screening modality for Down syndrome and other chromosomal abnormalities.

As mentioned above, new applications of ultrasound have made a considerable impact on our ability to provide prenatal diagnosis. Work in the early 1990s showed that first-trimester ultrasonography could be used to detect fetuses at increased risk for fetal chromosome abnormalities (225–227). However, further work showed that ultrasound screening, specifically the measurement of the nuchal translucency (Figure 26-7), could be applied to the screening of high- and low-risk women for fetal chromosome and structural abnormalities (225,228–231). Similar to the second-trimester ultrasonography, operator, gestational, and mechanical factors can alter diagnostic ultrasonographic outcomes (232,233). The measurement of certain maternal serum

**FIGURE 26-7** Prominent nuchal translucency (0.29 cm between asterisks) measured in fetus at 11.6 weeks gestation. Fetus found to have trisomy 21 by CVS. (Courtesy of Leiber Cohen, MD.)

markers, including free  $\beta$ -hCG, PAPP-A, AFP, hCG, and unconjugated estriol in various combinations, has been shown to provide an adequate, though not optimal, first-trimester screening protocol for fetal Down syndrome (233,234). It is the combination of first-trimester ultrasound and maternal serum analyte analysis that has profoundly altered the approach to screening for fetal Down syndrome and trisomy 18.

### 26.10.1 Ultrasound Screening for Fetal Down Syndrome: Second Trimester

Analysis of maternal serum analytes has been the mainstay of screening for fetal chromosome abnormalities for almost two decades (235). In 1987, Benacerraf and colleagues (236) reported that second-trimester fetuses with Down syndrome were more likely than normal fetuses to have a thickened nuchal skin fold and shortened femurs. Among more than 5500 fetuses evaluated, the detection rate was 75% with a specificity of 98%. When other structural abnormalities were added (e.g. atrioventricular canal), the sensitivity rose to 82%. Although such ultrasound markers have been confirmed by others, such correlations have not been universally observed (237–239). Although Vintzileos and Egan (240) suggested that second-trimester ultrasound can be used to modify second-trimester serum analyte screening outcomes for Down syndrome, Palomaki and Haddow (241) provided multiple screening and ultrasound concerns that would preclude the application of ultrasound in this manner. Indeed, a meta-analysis by Smith-Bindman and colleagues (242) showed that the various ultrasound markers, except for nuchal thickness, showed low sensitivities for fetal Down syndrome detection in the absence of overt structural anomalies. Although a meta-analysis may or may not be appropriate in assessing the utility of ultrasound markers, the conclusions were consistent with those of most individual reports (Figure 26-8).

### 26.10.2 Ultrasound Screening for Down Syndrome: First Trimester

The use of ultrasound for first-trimester screening for fetal Down syndrome and trisomy 18 has begun to gain wide acceptance in Europe and the United States. The association of prominent nuchal translucency and increased risk for fetal chromosome abnormalities has been well documented (225–227,243); however, it was Nicolaides and colleagues (230) who proposed the use of first-trimester nuchal measurement and first-trimester maternal serum analytes in a screening paradigm for fetal Down syndrome. Among 1273 women carrying singleton pregnancies who were undergoing first-trimester CVS, a nuchal measurement of  $\geq 3$  mm could identify more than 85% of trisomy fetuses with a false-positive rate of approximately 5%.

Further studies have shown that the incorporation of two serum analytes, PAPP-A and free  $\beta$ -hCG, can improve the screening of pregnancies for Down syndrome and trisomy 18. The detection rate of first-trimester biochemical screening is similar to second-trimester screening (244). However, a recent large multicenter trial (245) incorporating biochemicals (PAPP-A and free  $\beta$ -hCG) showed a detection rate for Down syndrome of 79% at a positive screening rate of 5% and for trisomy 18, a detection rate of 91% at a positive screening rate of 2%. A study from the United Kingdom demonstrated a 93% detection rate for fetal Down syndrome at a positive screening rate of 5.9% and a detection rate of 96% for all chromosome abnormalities at a 6.3% positive screening rate (246).

In addition to the aforementioned screening protocol, an integrated screening involving first- and second-trimester screening protocols is now available and has been reported to yield higher detection rates with lower positive screening rates (247,248). In addition, ultrasound and maternal serum analyte analyses from the first trimester have been correlated with adverse obstetrical outcomes including PAPP-A ( $\leq 5$ th percentile) associated

with an increased risk for spontaneous pregnancy loss before 24 weeks gestation, low birth weight, preeclampsia, gestational hypertension, preterm birth, stillbirth, preterm premature rupture of the membranes, and placenta abruption. In addition, nuchal translucency ( $\geq 99$ th percentile) and free-beta subunit hCG ( $\leq 1$ st percentile) were associated with an increased risk of spontaneous loss at or before 24 weeks gestation (249).

The FASTER trial was a large US multicenter study comparing first- and second-trimester combined screening and second-trimester quadruple screening (MSAFP, hCG, unconjugated estriol, and inhibin A), first-trimester combined (PAPP-A, hCG and nuchal translucency) resulted in a slightly higher detection rate of Down syndrome than second-trimester serum screening (83% vs 81%) (250).

To achieve higher rates of Down syndrome detection and a reduction in the false-positive rate (i.e. reduce the need for invasive testing), the *integrated* approach to screening can be used, which incorporates both the first- and second-trimester markers to adjust a woman's age-related risk of having a child with Down syndrome. These results are reported only after both first- and second-trimester screening tests are completed. In this integrated approach, the detection rate for Down syndrome (94–96% in the FASTER trial and 94% in the SUPUSS trial) is higher than either first- or second-trimester screening alone (248,250). A concern in using the integrated approach is that first-trimester results are withheld from the patient until completion of the second blood test. Thus, the patient does not have the opportunity of early (i.e. first-trimester) diagnostic testing, as well as compliance with a two-step screening process.

To allow the results of the first-trimester combined screening to be disclosed to the patient, two sequential screening strategies have been introduced, namely, *stepwise* and *contingent* screening. If the stepwise strategy is used, the patient is offered a diagnostic test (CVS or amniocentesis) if the risk of aneuploidy is greater than a predetermined cutoff point; if not, she proceeds with the quadruple screening and receives a recalculated final risk figure based on the first- and second-trimester measurements. In contingent sequential screening, women are stratified according to the initial adjusted Down syndrome risk; only women with an intermediate Down syndrome risk (e.g. between 1 in 30 and 1 in 1500) would undergo the second-trimester screening. Finally, some have used a “default” approach called *independent sequential screening*, which involves carrying out a combined test (PAPP-A, hCG and nuchal translucency) in the first trimester, followed by a quadruple screening in the second trimester, and calculating separate risks from each. This approach is considered invalid since the second-trimester test does not incorporate all the available risk-related information, and is therefore not recommended (251).

### 26.11 FETAL CELLS AND FETAL DNA IN MATERNAL BLOOD

The concept of identifying and isolating fetal cells or fetal DNA in maternal blood is one that has been evaluated by numerous groups around the world for the past three decades. Such technology would ostensibly permit more effective screening for a wide variety of chromosome and Mendelian disorders and allow for the noninvasive diagnosis of certain detectable fetal abnormalities. The presence of fetal cells in maternal blood was first documented by Walknowska and colleagues (252) when they found XY metaphases in the maternal blood of pregnant women carrying male fetuses. De Grouchy and Trubuchet (253) also reported male metaphases from pregnant women carrying male fetuses, and other groups followed (254–256). During the late 1970s, Herzenberg and colleagues applied flow sorting technology to enrich for fetal cells (257,258). Their experimental design used HLA-A2-negative women who had an HLA-A2-positive spouse (heterozygote or homozygote). Any A2-positive cells recovered by flow sorting presumably must be fetal in origin that antigen having been inherited from the father.

Subsequently, a number of centers around the world have investigated isolation and analysis of intact fetal cells from mothers' blood for prenatal diagnosis. Our group was successful in detecting fetal aneuploidies, including trisomies 18 and 21, by sorting for CD 71, glycophorin-A positivity, cell size and cell granularity followed by interphase FISH with chromosome-specific probes (259–264).

However, subsequent work by our and other centers failed to develop techniques or processes that would provide a consistent number of fetal cells amenable to successful diagnostic protocols. Indeed, an NICHD conference reviewed the current status of work in the field of fetal cells in maternal blood and provided a clear consensus of the inadequacy of the methods used to date (265). The rarity of fetal cells in maternal blood is likely an important factor in the inability to develop an effective screening program. However, this could be overcome by fetal cell culture, which if successful, could obviously increase the absolute number of fetal cells present.

In contrast to diagnosis of fetal aneuploidy using intact fetal cells isolated from maternal blood, detection of fetal Mendelian disorders by analysis of fetal cells does not necessarily require enrichment procedures (266). Polymerase chain reaction (PCR)-based technology alone may suffice because DNA from any fetal cell should be reflective of fetal status. A circumstance permitting detection of a Mendelian disorder through analysis of fetal cells or fetal DNA in maternal blood arises when the father is heterozygous (Aa) and the mother is homozygously abnormal (aa) for an autosomal-recessive trait. The normal allele, which may

or may not be transmitted by the heterozygous father, should be readily detectable. If blood from the homozygous mother reveals DNA of the normal paternal allele (A), the fetus could be deduced to be heterozygous. An example of PCR in maternal blood to detect autosomal-recessive disorder is identifying pregnancies at risk for fetal Rh(D) disease. The molecular basis for an individual's being Rh(D)-negative (dd) is usually a gene deletion, d representing lack of the DNA sequence that, if present, encodes D. If the mother is Rh-negative and the father is homozygous for Rh(D) (Rh-positive), all fetuses must be heterozygous (Dd); every pregnancy would then be a risk for RhD-isoimmunization. If the father is heterozygous, however, the likelihood is 50% that the fetus would inherit his RhD gene and, hence, be affected; the other 50% of pregnancies would not be at risk for Rh-isoimmunization. Nested primers can be constructed so that the CE sequence is concurrently amplified, allowing an "internal control" that assures lack of D is not the result of primers failing to anneal or absence of cellular DNA in the sample tested. Using such a strategy, Lo and colleagues (267,268) studied 57 RhD-negative women throughout pregnancy. All RhD-positive fetuses in the second and third trimesters were correctly identified; 10 of 12 in the first trimester were also detected.

Initially, the discussion regarding RhD and other Mendelian conditions implied that the fetal DNA to be analyzed is present in the nucleus. Actually, cell-free DNA is also present in maternal plasma and serum (268,269). Our group (270) as well as others (268) have shown Rh(D) DNA in maternal serum of Rh-negative women (dd) carrying heterozygous (Dd) fetuses. Indeed, the detection of free fetal DNA in maternal serum for prenatal RhD genotyping in cases of maternal alloimmunization is now beginning to be used clinically in Europe (271–273) and is actively being studied in the United States (274).

Most recently, noninvasive detection of trisomy 21 has been reported using cell-free fetal DNA in maternal blood. Chui and colleagues (275) used two protocols of multiplexed massively parallel sequencing of DNA molecules in maternal plasma. In their "8-plex sequencing" protocol, the detection rate among trisomy 21 cases was 68/86 (79.1%) and the false-positive rate among non-trisomy 21 cases was 6/571 (1.1%). In their "2-plex sequencing" protocol, the detection rate among trisomy 21 cases was 86/86 (100%) and the false-positive rate among non-trisomy 21 cases was 3/146 (2.1%). They concluded that multiplexed maternal plasma DNA sequencing could be used to rule out fetal trisomy 21 among high-risk pregnancies, and about 98% invasive diagnostic tests could be avoided in patients referred for amniocentesis or CVS for increased risk for fetal trisomy 21.

Ehrich and colleagues (276) reported a blinded study of 480 prospectively collected maternal blood samples from women undergoing CVS, second-trimester amniocentesis or pregnancy termination. After exclusion of 31

samples for insufficient DNA quantity or quality, or failed assay quality control parameters, 449 samples remained for analysis. Using multiplexed massively parallel shotgun sequence of cell-free fetal DNA, 39 trisomy 21 samples were correctly identified; one sample from an unaffected fetus was classified as trisomy 21. Thus, the test showed a 100% sensitivity (95% CI: 89–100%) and a 99.7% specificity (95% CI: 98.5–99.9%). In an accompanying editorial, Shulman (277) cautions that although the report of Chiu and colleagues (275) is encouraging, further studies, including economic feasibility studies, portability studies and larger studies to better assess the detection rate of this assay for fetal trisomy 21 are required before such technology is even incorporated into screening algorithms, let alone replace current screening protocols.

## 26.12 FUTURE DIRECTIONS

As our ability to use molecular technologies to delineate fetal abnormalities increases, the need for invasive and highly morbid procedures will decrease. However, as technology advances increase our ability to safely evaluate and access the embryo and early fetus, we will face daunting social and economic issues that will need to be addressed by the medical and lay communities.

With the increasing age of the obstetrical community (278), advanced maternal age as a screening strategy for Down syndrome is considerably inferior to combined serum and sonographic screening protocols (279). In view of the overall improvement in the safety of invasive testing in combination with the increasing complexity of community-based screening protocols for Mendelian disorders (e.g. cystic fibrosis) and emerging first- and second-trimester screening protocols for fetal chromosomal abnormalities, consideration for universal offering of invasive testing to all women, regardless of age or risk, is warranted and should be further explored. In fact, Harris and colleagues (57) showed that the universal offering of invasive prenatal diagnosis would be cost-effective.

The increasing number of fetal disorders that are amenable to prenatal screening and diagnosis alone will necessitate a change in our methods for patient counseling. Elias and Annas (168) first proposed an innovative paradigm, “generic consent for genetic screening,” to restructure the informed consent process in the post-Human Genome Project era. This model recognizes that screening for numerous genetic disorders will require concepts that avoid information overload and promote patient autonomy. The effective performance of prenatal diagnosis is limited as much by our ability to effectively communicate with our patients as it is by our technology.

## Biographies

**Sherman Elias, MD** is a Professor and past John J Sciarra Professor and Chair of the Department of Obstetrics and Gynecology of the Feinberg School of Medicine at Northwestern University. Previously, he was a Professor and Henry and Emma Meyer Chair in Obstetrics and Gynecology and Professor of Molecular and Human Genetics at Baylor College of Medicine in Houston (1994–1998), and the William G Arends Chair and Phillip and Beverly Goldstick Professor of the Department of Obstetrics and Gynecology and Professor of Molecular Genetics at the University of Illinois at Chicago (1998–2003).

Dr Elias has served as President of the Society of Gynecologic Investigation, Director of the American Board of Obstetrics and Gynecology, Secretary of the International Society for Prenatal Diagnosis, President of the Central Association of Obstetricians and Gynecologists, Vice President for Clinical Practice of the American College of Medical Genetics, and President of the American Association of Obstetricians and Gynecologists Foundation. Dr Elias has had continuous funding from the National Institutes of Health and other sources since 1987. He has been the recipient of the Basil O'Connor Award and the Jonas Salk Health Leadership Award in Research from the March of Dimes Birth Defects Foundation, the W K Kellogg National Fellowship Award, the Distinguished Alumnus Award from the University of Kentucky, and named a University of Illinois Scholar. He has authored over 375 articles, reviews and chapters and six books. Dr Elias' research focuses on prenatal genetic diagnosis, reproductive genetics and medical ethics.

Dr Elias is a native of Louisville, Kentucky. He earned Bachelor of Science from the University of Louisville and his Doctor of Medicine from the University of Kentucky. He served his internship in Obstetrics and Gynecology at Michael Reese Hospital in Chicago, and residency in Obstetrics and Gynecology at the University of Louisville, where he served as chief resident. He served two postdoctoral fellowships in Medical Genetics, the first in at Yale University and at the second at Northwestern University. He is a Diplomate of the American Board of Obstetrics and Gynecology and a Diplomate of the American Board of Medical Genetics.

**Lee P Shulman MD** is the Anna Ross Lapham Professor in Obstetrics and Gynecology and Chief of the Division of Clinical Genetics at the Feinberg School of Medicine at Northwestern University in Chicago, Illinois. He also serves as the Director of the Cancer Genetics Program of the Robert H Lurie Comprehensive Cancer Center of Northwestern University and the Co-Director of the Northwestern Ovarian Cancer Early Detection and Prevention Program. Dr Shulman is an Adjunct Professor in the Department of Medicinal Chemistry and Pharmacognosy at the University of Illinois at Chicago College of Pharmacy. He is a Fellow of the American College of Obstetricians and Gynecologists and a Founding Fellow of the American College of Medical Genetics.

Dr Shulman was graduated from Cornell University in 1979 with a BA degree in the College Scholar program. He then attended Cornell University Medical College where he received his Doctor of Medicine degree in 1983. Dr Shulman completed an internship and residency in Obstetrics and Gynecology at North Shore University Hospital—Cornell University Medical College in 1987 and served as Chief Resident during his final year. From there he completed a fellowship in Reproductive Genetics at the University of Tennessee, Memphis and then joined the Ob/Gyn faculty of the University of Tennessee, Memphis, becoming the Director of Reproductive Genetics in 1994. In 1999, he relocated to the University of Illinois at Chicago where he served as Deputy Head of the Department of Obstetrics and Gynecology, Director of the Divisions of Reproductive Genetics and Ambulatory Care Services and as Medical Director of the Center of Excellence in Women's Health.

Dr Shulman is a member of numerous regional, national and international organizations that pertain to the health and care of women. His work has been recognized regionally and nationally; most recently, he was included in the list of "Top Doctors" in Chicago (2007–2010) and the United States (2006–2010). He is the Editor-in-Chief of the *Yearbook of Obstetrics and Gynecology and Reproductive Medicine*, is a Contributing Editor for *The Journal of Reproductive Medicine* and the Executive Editor of the *Journal of Gynecologic Surgery*. He also serves on the editorial boards of *Prenatal Diagnosis*, *Contraception*, *Menopause*, and as a peer-reviewer for 32 other journals. Dr Shulman served at the Chair of the Board of Trustees of the Association of Reproductive Health Professionals from 2006 to 2008. A frequent contributor to the peer-reviewed and informational literature with over 130 peer-reviewed articles and over 50 book chapters, Dr Shulman's major research interests are in reproductive and cancer genetics, contraception, menopause and botanical interventions in women's health.

### 27.1 INTRODUCTION

Genetic screening is a search in a population for persons who possess genotypes that (i) are associated with disease or predispose to disease, (ii) may lead to disease in their descendants, or (iii) produce other variations not known to be associated with disease. The primary focus of this chapter is newborn genetic screening for inborn errors of metabolism. Neonatal screening provides a means of early recognition of disorders in order to initiate treatment where available and to reduce confusion, anxiety, and delay associated with late ascertainment. Genetic screening can be a source of epidemiological data regarding birth defects and can also lead to a substantial increase in our knowledge of the natural history and variability in the genetic disorder. In the past, the nature and number of newborn screening tests varied widely in different localities. Recent technological advances and increased public awareness, however, have led to a much greater standardization of the tests used, as well as the number and types of disorders screened. At the request of the Maternal and Child Health Bureau of HRSA (Health Resources and Services Administration), the American College of Medical Genetics (ACMG) developed a uniform panel of 29 disorders that should be included in all state screening panels [Web resource 1]. Since this recommendation was adopted in September 2005, all states have implemented the uniform panel, increasing coverage substantially [Web resource 2]. Based on cumulative data from state newborn screening programs, about 1 in 800 newborns is born with a condition for which screening and treatment are available.

### 27.2 HISTORICAL ASPECTS

Genetic screening as we know it dates from the 1960s. As early as 1908, however, Archibald Garrod stated that inborn errors of metabolism could be recognized "... by some strikingly unusual appearance of surface tissues or of excreta, by the excretion of some substance

which responds to a test habitually applied in the routine of clinical work, or by giving rise to obvious morbid symptoms." This observation was first applied on a population-wide basis to phenylketonuria (PKU), but only after two important advances. The first occurred in 1934 when Fölling described the association between PKU and mental retardation. The second occurred when Bickel and coworkers developed a phenylalanine-restricted diet that was shown to prevent the mental retardation seen regularly in untreated PKU. The remaining challenge was to identify PKU in the presymptomatic newborn infant so that the dietary intervention could be optimally effective. This challenge was met when Guthrie developed a bacterial assay for phenylalanine that required only a few drops of blood, easily obtainable from the heel of newborn infants and dried on filter paper. Routine newborn screening for PKU using this method began in Massachusetts in 1962 and, after a successful field trial, expanded widely in the United States and abroad. Guthrie subsequently introduced microbiological assays to screen for maple syrup urine disease (MSUD), homocystinuria, tyrosinemia, histidinemia, galactosemia, and other disorders. Paper chromatographic methods for general newborn screening of blood and urine amino acids were also introduced at this time. The frequencies of some of these traditionally-screened disorders are shown in Table 27-1. Citations for these historical statements can be found in the previous edition of this book (1).

The great advantage of Guthrie's newborn screening system resided in the specimen of blood dried on filter paper, now often referred to as the Guthrie specimen or Guthrie card. This specimen is easily collected, readily transported to a central testing laboratory, and can be used in many different tests. In the 1970s, for instance, Dussault and colleagues introduced newborn screening for congenital hypothyroidism by developing a radioimmunoassay for thyroxine (T4) that could be applied to the Guthrie specimen (2). More recently, DNA extracted from the dried blood has been used for molecular testing.

In the 1980s, many newborn screening programs added tests for the sickle-cell diseases (viz. sickle-cell anemia, hemoglobin SC disease, and  $\beta$ -thalassemia). This occurred after demonstration in a large clinical trial that prophylactic treatment with penicillin reduced by 84% the mortality caused by infections with *Streptococcus pneumoniae* that otherwise killed many infants with sickle-cell disease. In the 1990s, screening was added for biotinidase deficiency by assay of biotinidase activity and for congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency, which accounts for more than 90% of all cases, by immunoassay of 17-hydroxyprogesterone (17-OHP). In 2010, programs have expanded further to include screening for cystic fibrosis (CF) by immunoreactive trypsinogen (IRT)-based methods and for many disorders affecting amino acids, organic acids, and fatty acid oxidation using the newly introduced technology of tandem mass spectrometry (MS/MS) (3).

Newborn screening for PKU and other inborn errors using dried blood has spread widely throughout the developed world. Not only has the practice of newborn screening increased but also the number of disorders covered has increased dramatically. In the United States this coverage has extended from the traditional PKU congenital hypothyroidism, galactosemia, MSUD and homocystinuria to CAH, sickle-cell disease and other hemoglobinopathies and additional amino acid disorders, as well as the organic and fatty acid oxidation disorders. Most of this expansion has been possible because of the introduction of MS/MS into newborn screening. Unlike traditional blood spot tests measuring a single analyte to detect individual disorders, MS/MS technology can screen for 20 or more disorders in a single blood spot. As a result of this new technology, the ACMG has proposed that all newborn screening programs include at least 29 “core” disorders (4,5) and all programs in the United States now adhere to this recommendation (Table 27-2). In addition, 25 “secondary target” disorders were recommended and many programs include all or most of these as well. Still other new tests continue to be proposed, with much recent interest focused on those that are DNA based (4). In view of the continuing changes in neonatal screening, the reader should consult an appropriate Web site for the latest information substantially [Web resource 2].

## 27.3 COMPONENTS OF SCREENING PROGRAMS

### 27.3.1 Collection of Specimens

The newborn Guthrie blood specimen is currently used for newborn screening in the United States and, with few exceptions, all other countries. One exception is the Canadian province of Quebec, which still collects and tests newborn urine specimens in addition to the newborn blood specimen. Several programs outside the

**TABLE 27-1** Frequencies of Some Metabolic Disorders and Conditions Detected by Screening Newborn Blood

Disorder or Condition	Frequency
Hyperphenylalaninemias	
Phenylketonuria	1:13,000
Other hyperphenylalaninemia	1:20,000
Galactosemia	1:50,000
Biotinidase deficiency	1:72,000
Maple syrup urine disease	1:70,000
Hypermethioninemia (homocystinuria)	1:200,000
Hereditary tyrosinemia	Very low

United States collect cord blood for congenital hypothyroidism screening.

The Guthrie specimen is usually collected in the nursery from the lanced heel of the infant by allowing drops of blood to saturate the filter paper within designated circles. The specimen is air dried in the nursery and then placed in an envelope or a plastic bag for transport to the central testing laboratory. Occasionally, the blood specimen is transferred to the filter paper from a capillary tube or a venous specimen. In Quebec, parents collect the newborn urine specimen when the infant is 3 weeks old using a kit supplied at the time of nursery discharge. The parent collects the specimen by placing the filter paper between folds of a wet diaper and pressing the diaper to push urine into the specimen card (6). Newborn urine screening was discontinued in Australia and the United States because of uncertainties regarding medical significance of many of the findings (e.g. histidinemia, Hartnup disorder, cystathioninemia, hyperlysinemia, and sarcosinemia). It has largely been supplanted by MS/MS technology, which detects some disorders previously screened in urine (e.g. methylmalonic acidemia, propionic acidemia, and argininosuccinic acidemia) and others (e.g. fatty acid oxidation disorders (FAODs)) that were not previously covered.

### 27.3.2 Organization of Screening

All screening programs in the United States are organized on a state-by-state basis, in that the state determines the disorders to be screened. Specimens are sent to the state program, and the program conducts the follow-up. In most states, the specimen is tested by the state laboratory or in a contract laboratory designated by the state. Several regional programs have been formed within which each participating state sends specimens to a testing laboratory within the region yet maintains within the originating state all other elements of the screening program. Newborn screening was fully funded by the states when first established, whereas most programs now charge a fee that may or may not include follow-up, confirmatory testing, and/or genetic counseling. Screening outside the United States has usually been organized in a manner similar to that in the United States. Nevertheless,

**TABLE 27-2 Core Disorders Recommended for Screening by American College of Medical Genetics**

Disorder	Acronym	Primary Marker
Metabolic disorders detected using tandem mass spectrometry		
<b>Organic acid disorders</b>		
Beta-ketothiolase deficiency (mitochondrial acetoacetyl CoA thiolase deficiency)	BKT	C5:1/C5OH
Cobalamin defects A,B,C,D,E,F	CBL (A-F)	C3
Isovaleric acidemia*	IVA	C5
Glutaric aciduria I	GA-I	C5DC
3-Hydroxy 3-methylglutaryl-CoA lyase deficiency*	HMG	C5OH/C6DC
Multiple carboxylase deficiency*	MCD	C3/C5OH
3-Methylcrotonyl-CoA carboxylase deficiency	3MCC	C5OH
Methylmalonic aciduria (mutase)*	MMA	C3
Propionic acidemia*	PA	C3
<b>Fatty acid oxidation defects</b>		
Carnitine uptake defect (carnitine transporter defect)	CUD	C0
Long-chain hydroxyacyl-CoA dehydrogenase deficiency*	LCHAD/D	C16OH/C18:1OH
Medium-chain acyl-CoA dehydrogenase deficiency	MCAD/D	C8
Trifunctional protein deficiency*	TFP	C16OH/C18:1OH
Very-long-chain acyl-CoA dehydrogenase deficiency	VLCAD/D	C14:1/C14
<b>Amino acid disorders</b>		
Argininosuccinic aciduria (argininosuccinate lyase deficiency)*	ASA	Citrulline
Citrullinemia I (argininocuccinate synthetase deficiency)*	CIT-1	Citrulline
Phenylketonuria	PKU	Phenylalanine
Maple syrup urine disease*	MSUD	Leucine
Homocystinuria	HCY	Methionine
Tyrosinemia type I	TYR-I	Tyrosine
<b>Other metabolic disorders</b>		
Biotinidase deficiency	BIOT	Biotinidase activity
Galactosemia*	GALT	Total galactose, GALT activity
<b>Endocrine disorders</b>		
Congenital adrenal hyperplasia*	CAH	17-Hydroxyprogesterone
Congenital hypothyroidism	CH	T <sub>4</sub> , TSH
<b>Hemoglobin disorders</b>		
Sickle cell anemia	HbSS	Hb variants
Sickle cell disorder	HbS/C	Hb variants
Hemoglobin S/ $\beta$ -thalassemia	HbS/betaTh	Hb variants
<b>Other disorders</b>		
Cystic fibrosis	CF	Immunoreactive trypsinogen
Hearing	HEAR	Hearing test

GALT = Galactose-1-phosphate uridylyltransferase; T<sub>4</sub> = thyroxine; TSH = thyroid-stimulating hormone.

\*Can manifest acutely in the first week of life.

there are a few national programs, notably the national screening program in Japan. These programs are usually included in national health services.

### 27.3.3 Analysis of Specimens

The formerly widely used Guthrie-type assays have been replaced by MS/MS, which allows for coverage of far more disorders. The details of the bacterial inhibition assays are of historical interest (1). Galactosemia is identified by either an enzyme assay for galactose-1-phosphate uridylyltransferase (GALT) activity or, less often, a metabolite assay for total blood galactose, the combination of galactose and galactose-1-phosphate. The enzyme assay is limited to the detection of galactosemia due to GALT activity, whereas a metabolite

assay can identify galactosemia and the two other galactose metabolic disorders, galactokinase deficiency and uridine diphosphogalactose-4-epimerase deficiency.

Biotinidase activity is also measured by an enzyme assay in the dried blood specimen. In the semiquantitative assay used in screening (7,8), biotinidase releases *p*-aminobenzoate from the artificial substrate, biotinyl-*p*-aminobenzoate. Color-developing reagents added subsequently cause samples with biotinidase activity to become purple, whereas samples lacking biotinidase activity remain clear or straw colored.

Congenital hypothyroidism, CAH, and CF are screened by immunoassays for, respectively, T<sub>4</sub> and/or thyroid stimulating hormone (TSH), 17-OHP, and trypsinogen (9). Sickle-cell diseases are screened by

examination of hemoglobin mobilities using either isoelectric focusing or hemoglobin electrophoresis (9).

MS/MS has been adapted for newborn screening. Use of this method is increasingly widespread in screening programs throughout the world. It allows the simultaneous screening for most amino acid disorders as well as for many organic acid and fatty acid oxidation disorders in a single assay (10,11). The technology employs two mass spectrometers in tandem separated by a collision chamber (Figure 27-1). The mass of the ionized molecules is determined in the first spectrometer and, after fragmentation in the collision chamber, the molecules are identified on the basis of the fragmentation profiles in the second spectrometer (12). The data are analyzed by a computer program and electrically translated into a graph with representative peaks for each metabolite. MS/MS is replacing the single amino acid bacterial assays used previously to screen for amino acidopathies and is expanding coverage to include many organic acidopathies and fatty acid oxidation defects (Tables 27-2 and 27-3).

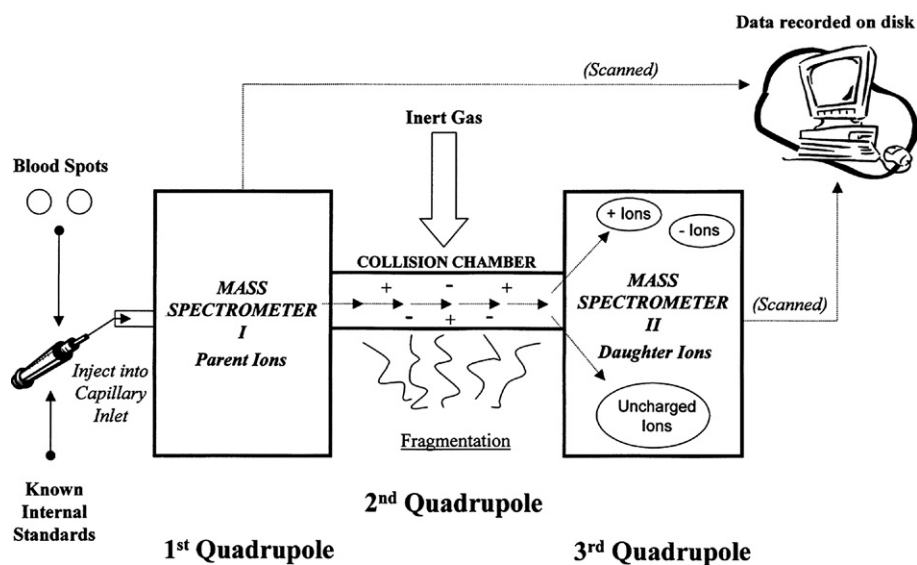

Almost all newborn screening has focused on an increase in an analyte, with notable exceptions being decreased T4, indicating congenital hypothyroidism, and enzyme assays for galactosemia and biotinidase deficiency, in which reduced activity is the indicator. Newborn screening programs led by the Mayo Clinic laboratory are considering identifying reduced analyte levels to indicate disorders in which the increase of an analyte is not currently identifiable. Examples are reduced methionine to indicate defects in methionine remethylation (13) and reduced citrulline to indicate proximal urea cycle disorders (N-acetylglutamate synthase (NAGS) deficiency, carbamylphosphate synthetase

(CPS) deficiency, or ornithine transcarbamylase (OTC) deficiency (14)).

Screening by direct analysis of DNA from Guthrie specimens has to date been limited to second-tier testing of specimens found to be positive by a primary, non-DNA screening method. Second-tier DNA screening by PCR analysis and detection of mutant alleles is currently in use for CF, medium-chain acyl-CoA dehydrogenase deficiency (MCADD), and galactosemia. A much more expansive application of DNA technology in routine newborn screening (e.g. exomic or whole genome screening) is a topic of much current discussion.

### 27.3.4 Interpretation of the Screening Results

Table 27-2 lists the core disorders identifiable by newborn screening, the acronym for each disorder, and the newborn screening abnormality, or primary marker, that might indicate the disorders as usually reported to the health care provider by the newborn screening program. All newborn screening reports indicating an abnormality should be followed up either by a repeat newborn screen, by obtaining specific confirmatory tests, or by referral to a metabolic center. The type of follow-up will probably be recommended by the newborn screening program coordinator and/or be indicated in the report. The recommendation is usually based on the magnitude of the abnormality or the potential immediate impact of the suspected disorder. Specifically, when the screening abnormality markedly deviates from the cutoff or the potential disorder can have a life-threatening neonatal effect (e.g. galactosemia or MSUD) the recommendation will be for immediate investigation or immediate referral to a metabolic center.

**FIGURE 27-1** Tandem mass spectrometry (MS/MS) in neonatal screening for inherited metabolic disorders. The mass of ionized molecules is determined in the first spectrometer and, following fragmentation in the collision chamber, the molecules are identified on the basis of the fragmentation profiles in the second spectrometer. The data are analyzed by means of a computer program and electrically translated into a graph with representative peaks for each metabolite.

**TABLE 27-3 Major Acylcarnitine Elevation in Expanded Newborn Screening and the Identified Organic Acid and Fatty Acid Oxidation Disorders**

Acylcarnitine	Abbreviation	Disorder
<i>Organic Acid Disorders</i>		
Propionylcarnitine	C3	Propionic acidemia Methylmalonic acidemia Cobalamin defect
Isovalerylcarnitine	C5	Isovaleric acidemia 2-Methylbutyryl-CoA dehydrogenase deficiency
3-Hydroxyisovalerylcarnitine	C5OH	3-Ketothiolase deficiency 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency 3-Methylcrotonyl-CoA carboxylase deficiency
Glutaryl carnitine	C5DC	Glutaric acidemia type I
<i>Fatty Acid Oxidation Disorders</i>		
Butyrylcarnitine	C4	Short-chain acyl-CoA dehydrogenase deficiency Isobutyryl-CoA dehydrogenase deficiency
Octanoylcarnitine	C8	Medium-chain acyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency
Tetradecanoylcarnitine	C14:1	Very-long-chain acyl-CoA dehydrogenase deficiency
Palmitoylcarnitine	C16	Carnitine palmitoyl transferase II deficiency Carnitine-acylcarnitine translocase deficiency Multiple acyl-CoA dehydrogenase deficiency
Hydroxypalmitoylcarnitine	C16:OH	Long-chain hydroxy acyl-CoA dehydrogenase deficiency
Carnitine (reduced)	C0	Carnitine transport defect

Conversely, an abnormality that is less deviant from the cutoff and that suggests a disorder without a neonatal phenotype might initially require only a repeat newborn screen.

To aid the physician in understanding these complex newborn screening findings and in deciding what to do when a report of an abnormality is received, the ACMG has developed “ACT Sheets,” 1–2 page explanations of newborn screening abnormalities and recommendations for follow-up. Accompanying each ACT Sheet is an algorithm to guide the follow-up testing and interpretation of the test results. The ACT Sheets and algorithms can be accessed through ACT Sheets and Confirmatory Algorithms [Web resource 3]. On the left of the site is “Short

cuts” and under that is a link to the ACT Sheet indicator. Click on that and you enter the site with an option for each type of abnormality. In addition, a full explanation of the metabolic disorders can be accessed at the GeneReviews web site [Web resource 4].

The majority of positive screening results is not due to a metabolic or other disorder. False positives frequently result from mild transient elevations in blood amino acids or acylcarnitines, which suggest the possibility of an amino acid, organic acid or fatty acid oxidation disorder in otherwise normal newborns. Premature infants receiving hyperalimentation or infants who are very ill often have multiple amino acid elevations, especially in the presence of severe liver dysfunction. Transient deficiencies of GALT produce false-positive results in galactosemia screening, especially during summer months because of inactivation of the enzyme by humidity and/or heat. Transient deficiencies of biotinidase activity, particularly in premature infants, may also be encountered in screening for biotinidase deficiency. Artifacts also account for many false-positive results. Multiple applications of blood to one area of the filter paper or the presence of blood clots can produce “caking” and falsely elevate the apparent concentrations of amino acids in screening assays. The frequency of false-positive results for some disorders such as PKU has decreased substantially with the introduction of MS/MS analyses, although the number of false-positive results overall has probably increased because of the much greater number of metabolites tested in the newborn specimen, more in some programs than in others. In view of the implications of false-positive results on the need for further testing and medical evaluation, and on parental anxiety, the establishment of appropriate cutoffs and care in the collection of the specimen are of great importance.

### 27.3.5 Confirmatory Tests

Importantly, an abnormal screening result, even when present on repeat testing, does not establish a specific diagnosis. An abnormality reflected by a positive screening test may have more than one possible genetic or nongenetic cause, and the etiology in each particular case must be ascertained. Confirmation of PKU, galactosemia, and other inborn errors of metabolism requires not only additional diagnostic tests but also rigorous clinical diagnostic evaluation before an appropriate plan of management can be formulated. DNA testing for confirmation of diagnosis and identification of mutant alleles is increasingly available for screened disorders. Direct DNA testing for diagnosis and genetic counseling is available for PKU and galactosemia among the “traditional” metabolic disorders, as well as for CAH, CF, MCADD, and the hemoglobinopathies, among the other disorders detectable by neonatal screening. A clear genotype/phenotype relationship has been described in some of the traditional metabolic disorders (e.g. galactosemia)

and has been identified in CAH, biotinidase deficiency, and the hemoglobinopathies. The ACMG ACT Sheets and algorithms indicated earlier provide guidance for confirmatory testing and interpretation.

## 27.4 POTENTIAL PROBLEMS IN NEWBORN SCREENING

Several important potential problems can affect the interpretation of the screening results and should be considered when deciding whether an infant with clinical evidence of disease should have additional metabolic tests and, if so, which tests to order.

### 27.4.1 False-Positive Results

Most positive results in newborn screening are transient aberrations not caused by a metabolic disorder or any other pathologic state. In some instances, the transient abnormality is associated with an identifiable temporary influence, such as antibiotic therapy, prematurity, or postprandial status, but often no cause is identified. These transient abnormalities are usually of mild degree. The cutoff or threshold level selected for the purpose of suspecting the presence of a metabolic disorder is usually a level that presumably will be exceeded by all affected infants, reflecting the high priority set on achieving maximum test sensitivity. The cutoffs, along with test sensitivity (i.e. the probability that a person with the disorder will have a positive test result) and specificity (i.e. the probability that a person without the disorder will have a negative test result), and positive predictive values (PPVs) (i.e. the proportion of persons with positive test results who actually have the disorder) are currently being analyzed in extensive national and international collaborations (14). These data will also be of great value for reducing the frequencies of false-positive and false-negative results.

False-positive results not only add to the expense and workload of newborn screening but also produce great anxiety in the parents of infants thus identified. Parents deserve simple and clear explanations of the reasons that the additional specimens are requested. Some newborn screening programs distribute specially prepared written explanations in advance to physicians or include them with requests for follow-up specimens. A study of expanded newborn screening for biochemical genetic disorders evaluated 50 children identified with inborn errors, 94 screened children with false-positive results, 81 screened children with normal results, and their respective parents. False-positive findings in newborn screening generated anxiety in parents, as indicated by a twofold greater likelihood that their children would have an emergency department visit or hospitalization compared with screened children with normal results. Mothers of children in the false-positive group compared with mothers of children with normal screening results

attained higher scores on the Parental Stress Index and the Parent–Child Dysfunction scale (6,15).

A major advantage of new technologies is the potential for reducing false-positive results. MS/MS provides a metabolite profile rather than only the single metabolite levels measured by the bacterial assays. In screening for PKU, for instance, it is the ratio of phenylalanine to tyrosine that best distinguishes the infant with PKU from the much larger number of infants with only transient hyperphenylalaninemia. MS/MS also provides a leucine/isoleucine:alanine ratio that distinguishes infants with MSUD from those with a transient increase in the blood leucine concentration. False-positive rates for MCADD screening can be reduced using an MS/MS profile that includes C6 and C10:1 acylcarnitines along with the C8 analyte.

Second-tier testing of newborn specimens exhibiting abnormal primary screens is increasingly being performed in screening laboratories in order to distinguish the infant with a true disorder from infants who have transient increases or who have a benign variant of the disorder. Second-tier screening has traditionally been practiced for galactosemia and congenital hypothyroidism. A specimen with an increased galactose concentration can be retested by performing a spot enzyme assay for GALT activity to distinguish the infant with classical galactosemia from infants with benign variants or transient increases in galactose as well as the infant with another galactose metabolic defect. Infants with low T4 levels on primary screening are encountered frequently, and their specimens can then be assayed for TSH to identify those with congenital hypothyroidism who will have both a low T4 and a high TSH. DNA analysis is increasingly being used now for second-tier testing. This began with screening for CF to distinguish infants with CF from those with only transient increases in IRT. A secondary molecular assay for F508del, the mutant allele present on 70% of CF chromosomes, along with a panel of the most frequent CF alleles, eliminates most of the false-positive results. IRT/DNA algorithm assays detect the 23 mutations currently recommended by ACMG (16). This approach usually involves referral of newborns with IRT values above the cutoff and 1 or 2 CFTR mutations for sweat testing in a CF center. More recently, second-tier DNA testing has been extended to galactosemia screening (17) by some programs. The Duarte mutation (N314D), for example, is a frequent source of benign initial positive screens. Screening begins with quantitative GALT enzyme analysis. If the quantitative GALT enzyme value is consistent with a diagnosis of pronounced deficiency or carrier status for galactosemia, DNA analysis of the *GALT* gene 6-mutation panel is performed to detect the four most frequently encountered classic galactosemia alleles (Q188R, S135L, K285N, and L195P) in addition to the N314D (Duarte) and L218L (Los Angeles) variants. Second-tier DNA testing has also proved useful in biotinidase screening (18). For specimens that show increased 17-OHP in the primary screen for CAH, second-tier testing by MS/MS has recently been

introduced (19). The infant with CAH is likely to have a low cortisol level determined by this method. Second-tier testing methods for isovaleric acidemia and methylmalonic acidemia have also been developed (20).

### 27.4.2 Early Newborn Screening

All newborn screening programs require or strongly recommend collection of the Guthrie specimen before the neonate is discharged from the hospital. This essentially guarantees that the newborn will be screened. Traditionally, the specimen would be obtained on the second or third day of life, but the discharge of newborns at or before 24 h of age means that many neonates are being screened “early” relative to the traditional parameters of newborn metabolic screening. Early discharge has revived concerns about missing affected infants by screening them prior to the time when their metabolic abnormality becomes detectable and has led to the recommendation for collection of a second blood specimen from infants initially tested at or before 24 h. Most disorders, including PKU, can be identified before 24 h of age. Early identification of isovaleric acidemia has been demonstrated (21) and suggests that other organic acid disorders, as well as fatty acid oxidation defects detected by elevations of acylcarnitine derivatives, could also be identified early. Biotinidase deficiency and galactosemia can be detected in Guthrie specimens collected before 24 h of age because the corresponding enzyme assays are not affected by the timing of specimen collection. In contrast, detection of some disorders is adversely affected by early specimen collection. The hypermethioninemia required to detect homocystinuria due to cystathionine  $\beta$ -synthase (CBS) deficiency usually does not develop until at least 24 h of age or later (22). Detection of congenital hypothyroidism may also be compromised in the early specimen. The current trend is to insist on collection of the initial specimen at discharge regardless of age and to recommend the collection of a second Guthrie specimen at no later than 7 days of age from infants discharged “early,” that is, prior to 24 h of age (Table 27-4).

### 27.4.3 Transferred and Transfused Infants

Failure to collect the newborn screening specimen is not uncommon among infants transferred to a special care

nursery, especially when this transfer is to another hospital. Ironically, the transfer may be necessitated by the symptoms of a disease identifiable in routine screening, such as galactosemia or MSUD. To guard against this omission, the initial screening specimen should be collected before transfer and a second screening specimen collected at discharge (Table 27-4).

The infant who receives a blood transfusion is also vulnerable to missed diagnosis in newborn screening. Notably at risk are the diagnoses of galactosemia and sickle-cell disease, both of which depend on identifiers in the red blood cell (viz. lack of GALT enzyme activity and the presence of hemoglobin S, respectively). Donor erythrocytes in the transfused blood will mask these abnormalities by providing normal red blood cells to the affected infant. The initial screening specimen should be collected prior to any transfusion and a second screening specimen collected at about 2 months of age when the infant has replaced most of the donor erythrocytes with endogenous red blood cells (Table 27-4).

### 27.4.4 Missed and Uncovered Disorders

A common misconception is that all infants with metabolic disorders for which newborn screening is conducted are detected in the screening process. Although most are detected, an occasional infant with PKU, congenital hypothyroidism, or another screened disorder is missed (23). There are a number of reasons why these infants can be missed, including delay in appearance of the identifier (e.g. lack of elevated blood methionine in homocystinuria) (22). FAODs are among the most likely to be missed, either because the initial screen is normal (24) or because the repeat specimen to evaluate an abnormal initial result is normal (25). Laboratory error must also be considered. A recent addition to the causes of not identifying an infant in newborn screening is the “opting out” of expanded (MS/MS) newborn screening by a parent (26). Based on the presumption of a normal newborn screen and even after receiving a normal newborn screening report, it is important not to assume that an infant with a clinical phenotype compatible with one of the screened metabolic disorders is unaffected. Evaluation of these patients should include tests for all relevant metabolic disorders, without excluding the ones covered by newborn screening, in order to avoid serious delays in diagnosis and treatment.

Misconceptions about newborn screening also extend to the range of coverage for metabolic disorders. Knowledge that newborn screening includes metabolic disorders can be misinterpreted as indicating that all metabolic disorders are covered. This misinterpretation can lead to the omission of metabolic testing in a clinically abnormal infant who otherwise would receive these tests, resulting in delays in diagnosis and therapy.

**TABLE 27-4 Specimen Collection in Newborn Screening**

Neonate	Initial Specimen	Repeat Specimen
Normal	$\geq 24$ h <24 h	No $\leq 7$ days
Low birth weight	3 days	No
Transferred	At transfer	Discharge
Transfused	Before transfusion	2 months

## 27.5 DISORDERS AND CONDITIONS DETECTED BY NEWBORN BLOOD SCREENING

Although detailed descriptions of these disorders are beyond the scope of this chapter, aspects especially pertinent to screening are considered below.

### 27.5.1 Phenylketonuria and Hyperphenylalaninemia
